A recent segmentation study revealed that the INL of the macular area is more affected by disease duration.<sup>69</sup> GCL thickness is inversely correlated with disease duration and disease severity.

The analysis of peripapillary RNFL thickness showed a reduction in average RNFL thickness and a significant thinning of the nerve fibers entering the temporal quadrant of the optic disc.<sup>70,71</sup>

The eye contralateral to the more affected body side is more affected than the ipsilateral eye, suggesting an asymmetry of the neurodegenerative process that involves both the substantia nigra and the ipsilateral eye.

The pattern of axonal loss is similar to that typically seen in Leber's hereditary optic neuropathy (LHON) and dominant optic atrophy (DOA), where the temporal fibers belonging to the papillomacular bundle are characteristically susceptible (Fig. 9.2.5).<sup>72</sup> Both diseases are associated with a mitochondrial respiratory chain complex I defect, which is also recognized as a key feature in the pathogenesis of sporadic and genetic forms of PD. This common underlying mechanism explains the similar pattern seen in patients with PD and those with LHON and DOA.

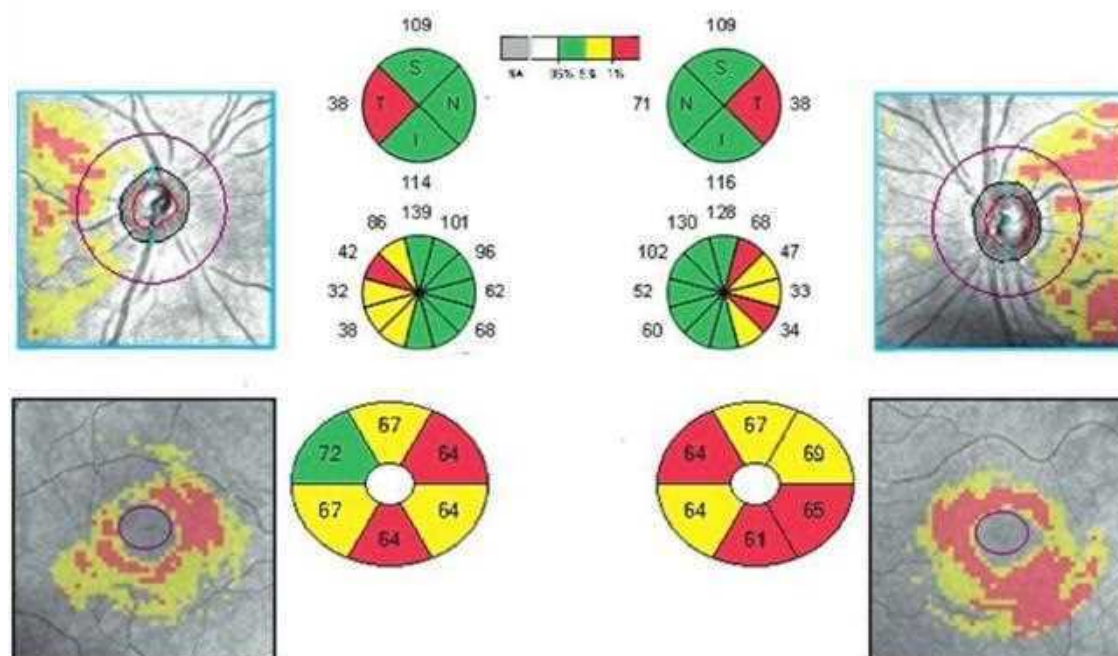

A recent meta-analysis containing a total of 644 eyes of PD patients and 604 eyes of healthy controls reported significant peripapillary RNFL thinning in all the quadrants in PD patients.<sup>73</sup>

The role of a specific PD neuropathology in the retina is controversial, and clear evidence of alpha-synuclein deposition is still missing. The most consistent link hypothesized between subclinical optic nerve involvement in PD and the major mitochondrial optic neuropathies in LHON and DOA is based on complex I dysfunction and altered mitochondrial dynamics.<sup>72</sup>

### ALZHEIMER'S DISEASE

Alzheimer's disease (AD) was first noted to produce optic neuropathy in the late 1980s.<sup>74–76</sup> Subsequent studies with time-domain OCT have shown a significant thinning of the peripapillary RNFL in patients with AD and mild cognitive impairment (MCI), thus confirming previous histopathological investigations (Fig. 9.2.6).<sup>77–79</sup> A recent meta-analysis<sup>80</sup> including 380 patients with AD—68 with MCI and 293 healthy controls—showed a significant mean RNFL thinning in subjects with MCI (weighted mean differences in  $\mu\text{m}$ , WMD = −13.39) and in subjects with AD (WMD = −15.95)

**Fig. 9.2.6 Optical Coherence Tomography in Alzheimer's Disease.** Diffuse macular ganglion cells and temporal, superotemporal, and inferotemporal peripapillary retinal nerve fiber layer reduction in a 73-year-old man affected by Alzheimer's disease.

compared to healthy controls. The meta-analysis showed that significant RNFL thinning is detectable in all quadrants ( $P < 0.0001$ ) in AD patients, and the reduction is more pronounced in the superior quadrant (WMD =  $-24.0$ ) followed by the inferior (WMD =  $-20.8$ ), the nasal (WMD =  $-14.7$ ), and the temporal (WMD =  $-10.7$ ) quadrants. In subjects with MCI, a significant reduction in RNFL was observed in the inferior (WMD =  $-20.22$ ,  $P = 0.0001$ ), nasal (WMD =  $-7.4$ ,  $P = 0.0001$ ), and temporal (WMD =  $-6.88$ ,  $P = 0.01$ ) quadrants, with the exception of the superior quadrant (WMD =  $-19.45$ ,  $P = 0.06$ ).

Macular volume, as measured by OCT, also seems to be reduced in comparison to healthy subjects with the reduction being associated with the severity of cognitive impairment.<sup>79</sup> However, in a calculated linear discriminant function, the combination of the peripapillary RNFL parameters seems to show the highest diagnostic accuracy in AD compared to macular thickness measurements.<sup>81</sup>

A mouse model of AD showed accumulation of beta-amyloid in the inner retinal layers and dendritic atrophy of the retinal ganglion cells.<sup>82</sup> GCL and inner plexiform layer (IPL) thinning was detected in AD patients and found to be more sensitive than RNFL thinning to distinguish AD patients from controls (see Fig. 9.2.6).<sup>83</sup> GCL and IPL thinning was associated with AD duration and severity.<sup>84</sup>

## FRIEDREICH'S ATAXIA AND OTHER RARE NEUROLOGICAL SYNDROMES

Friedreich's ataxia has been long regarded as mitochondrial hereditary ataxia with cerebellar and motor disorders. However, Friedreich's ataxia patients can also develop optic neuropathy characterized by reduced RNFL thickness. The diffuse and progressive fiber loss does not initially result in any perimetric damage, which occurs only in later stages.<sup>42</sup> Ganglion cell loss is uniformly scattered over the entire ganglion cell pool without the typical selectivity shown by other mitochondrial optic neuropathies, where the papillomacular bundle is preferentially affected. Furthermore, in addition to loss in the anterior visual pathway, degeneration is also found in the optic radiations.<sup>85</sup>

OCT studies have also been published in other rare neurological syndromes, such as spinocerebellar ataxia, Wolfram syndrome, autosomal recessive spastic ataxia of Charlevoix-Saguenay, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL), hereditary spastic paraplegia due to SPG7 mutations, DNA (cytosine-5)-methyltransferase 1 (DNMT1), and Jansky-Bielschowsky disease. For a more comprehensive review, please refer to a recent monography.<sup>2</sup>

## HEREDITARY OPTIC NEUROPATHIES

### LEBER'S HEREDITARY OPTIC NEUROPATHY

LHON is a maternally inherited cause of blindness usually manifested in young adults that is caused by one of several mutations in the mitochondrial genome.<sup>86</sup> OCT has been used to study changes in RNFL thickness in both unaffected carriers and patients affected with LHON. In unaffected carriers, compared to the control group, a significant increase in thickness was observed in the temporal quadrant along with a smaller increase in the inferior quadrant.<sup>87</sup> In the acute phase, and more precisely within 6 months after onset of the visual defect, RNFL analysis shows thickening in the superior and inferior quadrants, whereas the temporal quadrant shows no significant differences compared to the controls (Fig. 9.2.7).<sup>88</sup>

Finally, once optic atrophy has set in, all quadrants of the optic disc show a thinning of the fibers (see Fig. 9.2.7).<sup>88</sup> The lack of any thickening of the papillomacular bundle in the acute phase has been interpreted as initial atrophy of the fibers in this sector following the edematous phase. A study conducted on patients before, during, and after the acute phase identified the temporal sequence of RNFL during the early acute phase (Fig. 9.2.8).<sup>89</sup> In the transition from the presymptomatic phase to the acute phase, the temporal fibers begin to thicken then start thinning at the beginning of the symptomatic phase. This finding confirms the preferential involvement of the small fibers of the papillomacular bundle. A simultaneous thickening takes place in the inferior sectors for the first 3 months, after which the fibers begin to thin (Fig. 9.2.9). This finding is in line with the larger temporal and inferior thickening observed in asymptomatic subjects. The superior and nasal sectors are involved in a subsequent stage and show thickening after 3 months, when the other sectors are already in the atrophic phase. The acute phase of LHON has proven to be a more dynamic and progressive phase than was previously envisaged, being characterized by a series of events lasting at least 3 months.<sup>89</sup>

OCT analysis of the RNFL in childhood LHON shows that in acute forms there is diffuse fiber atrophy affecting all quadrants.<sup>90</sup> This finding holds for all acutely affected eyes in both bilateral and unilateral forms. In this case, the childhood forms do not differ from adult-onset ones. Slowly progressive forms show a significant fiber reduction in the temporal quadrant, which extends, albeit insignificantly, to the inferior quadrant, with relative preservation of fibers in the other sectors. Finally, in eyes with a subclinical course of disease, the situation in terms of fiber loss is comparable to that of slowly progressive forms, with preferential involvement of the temporal quadrant and, to a lesser extent, of the inferior quadrant.<sup>90</sup> In these two atypical forms, the ophthalmoscopic picture and pattern of

**Fig. 9.2.7 Fundus Appearance and Retinal Nerve Fiber Layer Analysis in Acute Asymmetric Leber's Hereditary Optic Neuropathy Patient.** Right eye (A–B) shows inferotemporal thinning of fibers and swelling of the supero-nasal quadrants. Left eye (B–C) shows an initial thinning of temporal fibers with swelling the other quadrants.

**Fig. 9.2.8 Longitudinal Peripapillary Retinal Nerve Fiber Layer (pRNFL) and Macular Ganglion Cells-Inner Plexiform Layer (GC-IPL) Changes in Acute Leber's Hereditary Optic Neuropathy.** Thickness variation is expressed as percentage of reduction with respect to the presymptomatic examination. Note the different natural history of pRNFL, which shows early thickening and late thinning in comparison to the early GC-IPL thinning. (Modified from Balducci N, Savini G, Cascavilla ML, et al. Macular nerve fibre and ganglion cell layer changes in acute Leber's hereditary optic neuropathy. *Br J Ophthalmol* 2016;100:1232–7.)

fiber loss, though clinically reminiscent of DOA, are more typical of LHON since the damage remains limited to the papillomacular bundle without extending to other fibers, as occurs in late DOA.

Analysis of the optic disc reveals that optic nerve size varies significantly according to clinical form. Patients with acute onset show a significantly smaller disc than healthy subjects or subjects with a slowly progressive course.<sup>90</sup>

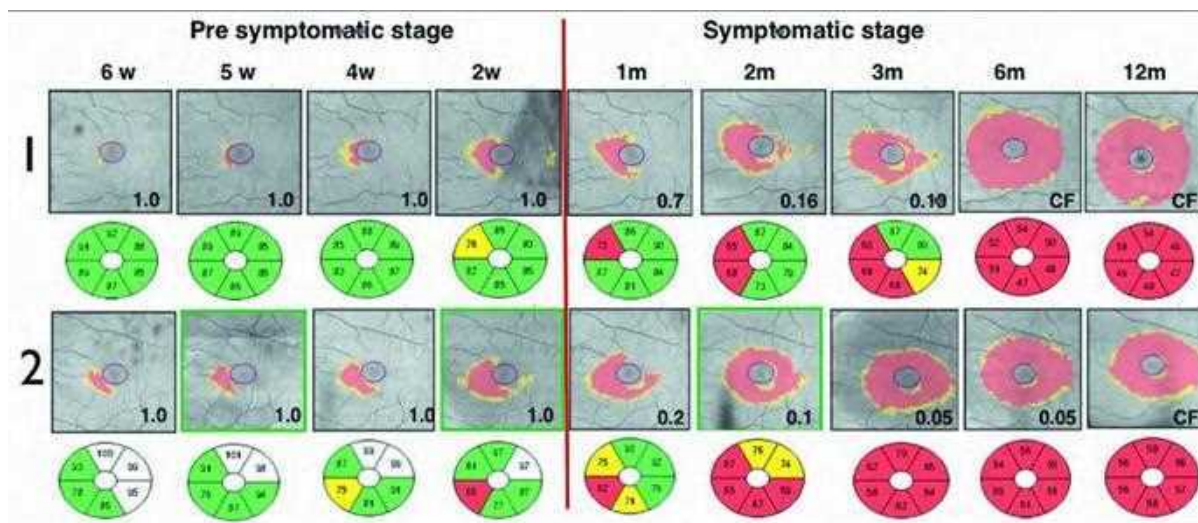

A small optic disc with a small cup-to-disc ratio, defined as a “disc at risk,” has been viewed historically as a predisposing factor for NAION. With respect to LHON, a large optic disc represents a favorable prognostic factor in terms of both protecting against the development of the disease and improving the visual prognosis in affected patients. In both diseases, onset is an acute event that could be linked to the mechanical phenomenon

of fiber crowding in the ONH.<sup>91</sup> In slowly progressive forms of LHON and DOA, as discussed later, the clinical course is associated with a slow process of axonal degeneration, which does not imply a mechanical crowding phenomenon.

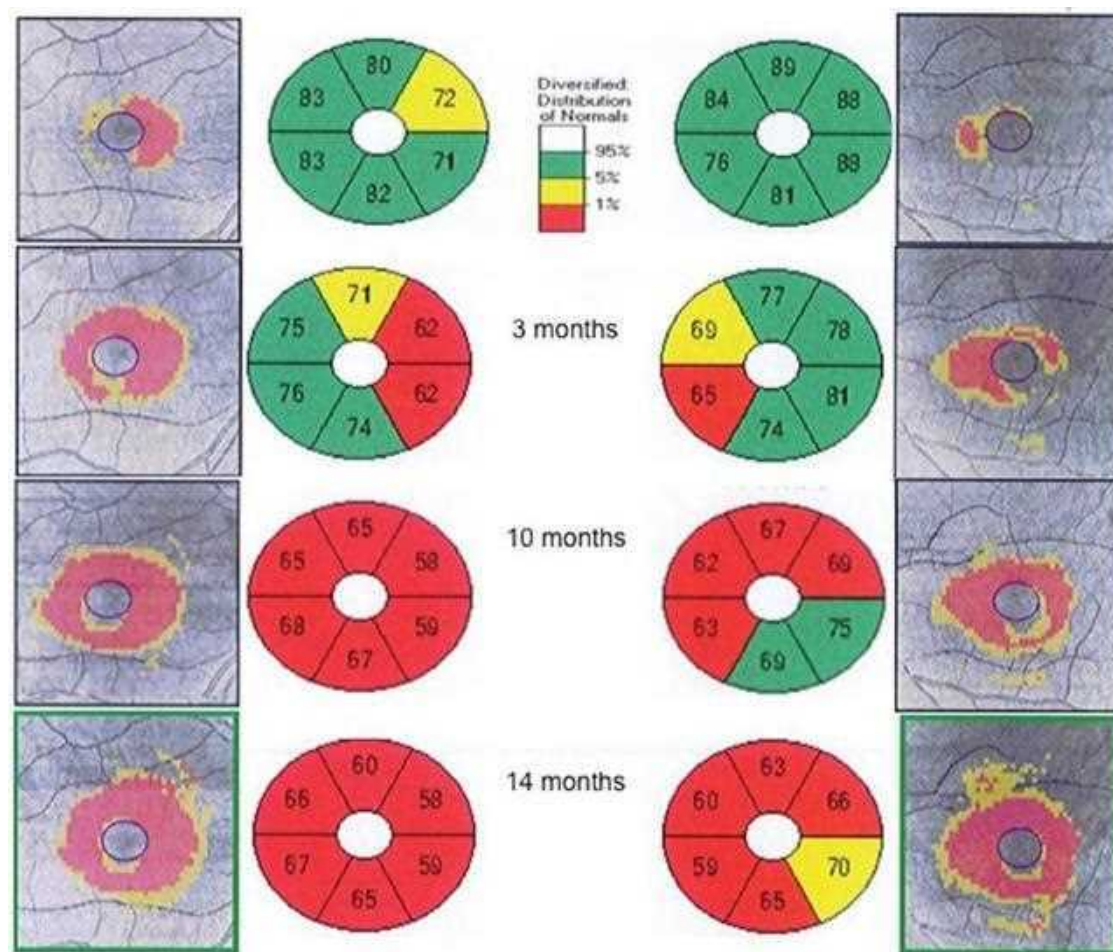

Macular thickness in LHON is reduced before RNFL thinning, and this reduction follows a particular sequence: within 3 months after LHON onset, macular thickness was reduced compared to healthy controls in the superior, nasal, inferior, and temporal quadrants of the inner ring and in the nasal quadrant of the outer ring. Then, within 3–6 months the temporal quadrant of the outer ring also became thinner. Finally, 6 months after visual loss, macular thickness was reduced in all the quadrants.<sup>92</sup>

The macular thickness reduction is due to GCL reduction, which is detectable before RNFL thinning.<sup>93</sup> Specifically, analysis of GCL 6 weeks

**Fig. 9.2.9** Longitudinal Deviation and Sectorial Map Changes of Two Patients Affected by Leber's Hereditary Optic Neuropathy Followed From the Pre-symptomatic to the Chronic Stage. Note the similar early nasal thinning detected in the deviation map during the presymptomatic stage and its progression in a centrifugal and spiral pattern resembling the anatomic distribution of the papillomacular bundle fibers (*m*: months after onset of visual loss; *w*: weeks before onset of visual loss). (From Balducci N, Savini G, Cascavilla ML, et al. Macular nerve fibre and ganglion cell layer changes in acute Leber's hereditary optic neuropathy. *Br J Ophthalmol* 2016;100:1232–7.)

**Fig. 9.2.10** Progressive Ganglion Cell Layer (GCL) Thinning in Toxic Optic Neuropathy. A 40-year-old man with a history of smoking and alcohol consumption was placed on antiretroviral drugs for HIV and tetracycline for syphilis. The initial thinning in GCL was at the level of papillomacular bundle, which worsened over time. The patient recovered vision after stopping the toxins and receiving antioxidant therapy.

before onset of visual loss shows thinning of the inner ring of the nasal sectors, detectable with the deviation map. This defect progressively extends to the inner ring of the inferior sector and enlarges to the outer ring of the nasal sectors over a period of 1 month.<sup>10</sup> Notably, GCL loss may represent the first sign of LHON conversion from the unaffected carrier stage to the acute stage. Later, the defect enlarges, reflecting the anatomical course of papillomacular fibers and a diffuse GCL thinning is detectable 6 months after visual loss (see Fig. 9.2.9).

## DOMINANT OPTIC ATROPHY

A hereditary degenerative optic neuropathy similar to LHON is dominant optic atrophy. The latter is due to a mutation in the nuclear genome and has a clinical picture more insidious than that of LHON.<sup>86</sup> OCT analysis of the retinal peripapillary nerve fiber layer reveals diffuse fiber atrophy affecting all quadrants (Fig. 9.2.10).<sup>94,95</sup> In patients with DOA, RNFL thinning is more evident in the temporal and inferior quadrants, with the reduction (compared to the control group) of 49.7% (eye with better vision) and

52.4% (eye with worse vision). The thickness reduction, though present, is smaller in the superior quadrant (28.4%–31.4%) and nasal quadrant (26.3%–28.3%).<sup>95</sup> This pattern of RNFL atrophy is generally comparable to the pattern observed in LHON, confirming the vulnerability of the small fibers of the papillomacular bundle as a pathognomonic sign of mitochondrial optic neuropathies (Fig. 9.2.11).

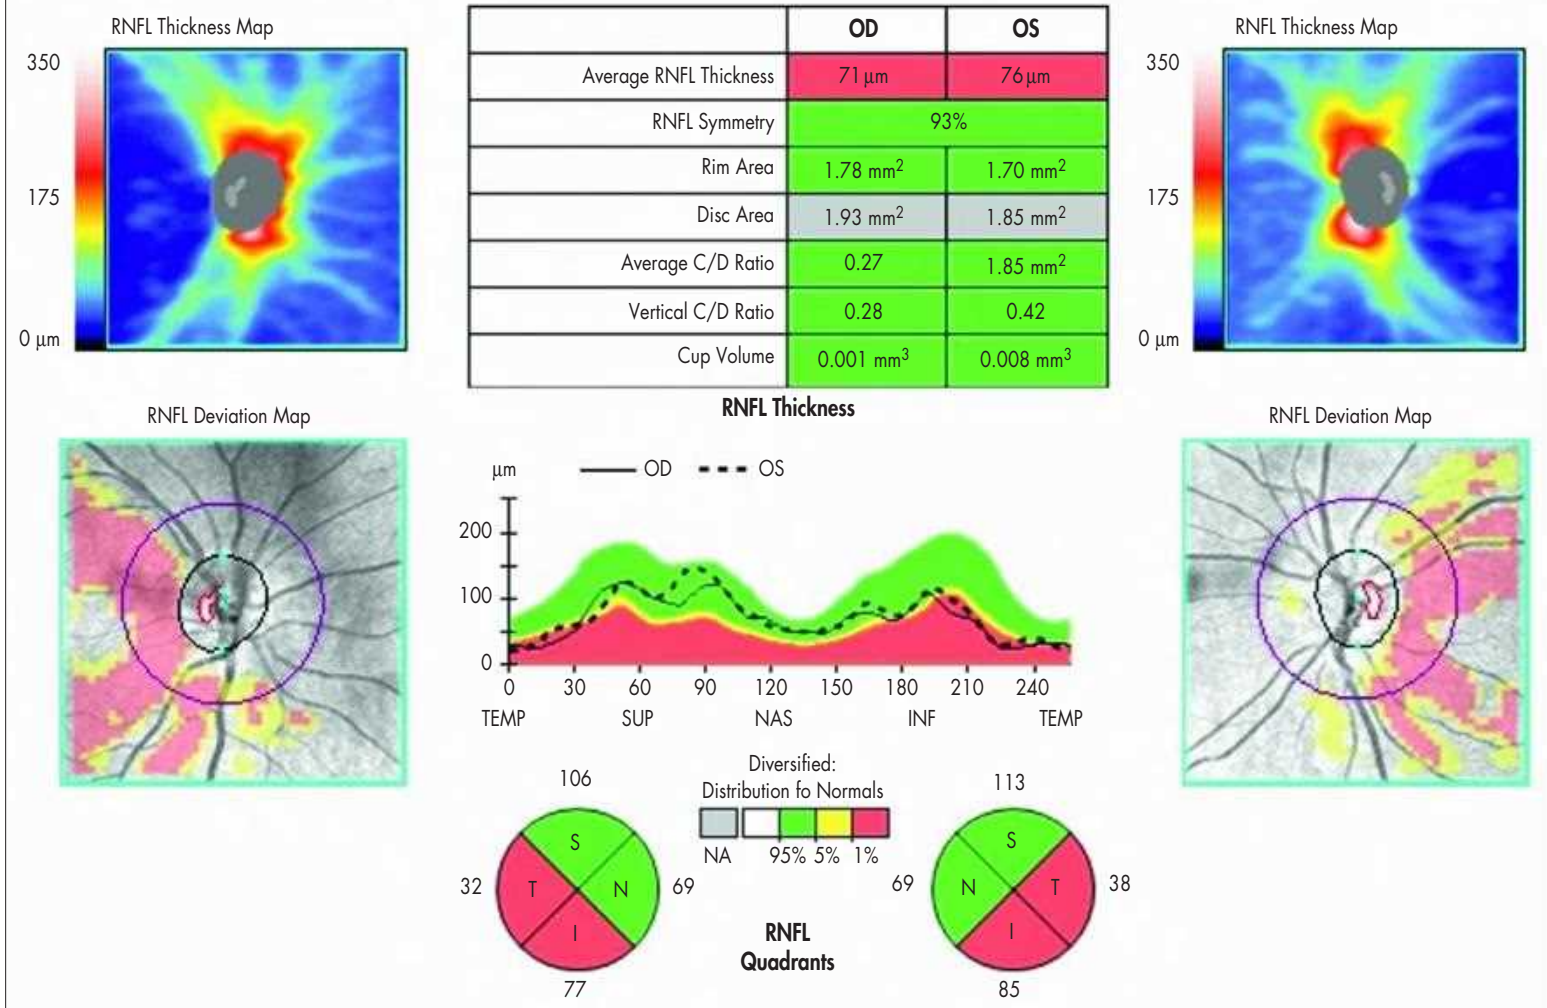

The progressive fiber loss in affected patients is similar to that normally occurring with age. In fact, in patients with DOA, the average decrease in fibers is 0.19 microns per year, comparable to the loss observed in different control groups: 0.16–0.25–0.22.<sup>94,95</sup> This result is correlated with the anatomical conformation of the optic nerve.<sup>95</sup>

Optic disc size is an important parameter in DOA. In DOA patients, the disc area is significantly smaller when compared with that of healthy controls.<sup>96</sup> In patients who are OPA1 mutation carriers, the disc area and vertical and horizontal disc diameters are significantly smaller than those of healthy controls (Fig. 9.2.12). By stratifying these results according to OPA1 mutation, it is possible to identify different degrees of optic disc size, where the mutations range from those associated with a normal optic

## ONH and RNFL OU Analysis: Optic Disc Cube 200×200

OD ● OS ●

**Fig. 9.2.11 Optical Coherence Tomography (OCT) Analysis in Dominant Optic Atrophy (DOA) Patient.** Both eyes show inferotemporal thinning of fibers.

disc size to those associated with much smaller sizes and more severe clinical features of DOA (see Fig. 9.2.12). The proposed hypothesis is that OPA1 expression regulates apoptosis, thereby playing an important role in the embryonic development of the eye and contributing to the determination of optic disc size and conformation. Ultimately, optic nerve size may be important in the phenotypic expression of the disease, the quantity of fibers present at birth, and the determination of the age of onset, progression, severity, and penetrance of DOA.<sup>96</sup>

Optic disc size is thus an important parameter in DOA, one that requires a careful differential diagnosis to distinguish DOA from optic nerve hypoplasia. DOA in isolated form is not associated with developmental abnormalities of the central nervous system.

Retinal thickness is reduced in DOA when compared to healthy controls.<sup>97</sup> The retinal thinning is due to RNFL and GCL reduction, whereas the other retinal layers do not differ from controls.

In DOA, the thinning of GCL is the earliest pathological event and is diffusely reduced in all macular sectors.<sup>97,98</sup> Genotype/phenotype correlation was demonstrated—based on specific OPA1 mutation, different grades of GCL thinning correlated with visual loss.<sup>98</sup> Different GCL thickness also declined with age.<sup>99</sup>

## Nutritional and Toxic Optic Neuropathies

Nutritional and optic neuropathies are characterized by dyschromatopsia and by painless, progressive, symmetric, and bilateral visual loss due primarily to selective damage to the papillomacular bundle. Malnutrition associated with alcohol abuse may be the most common cause of nutritional optic neuropathy. Common drugs causing toxic neuropathies are ethambutol, chloramphenicol, linezolid, erythromycin, streptomycin, antiretroviral, amiodarone, infliximab, quinine, dapsone, pheniprazine, suramin, and isoniazid.<sup>100</sup>

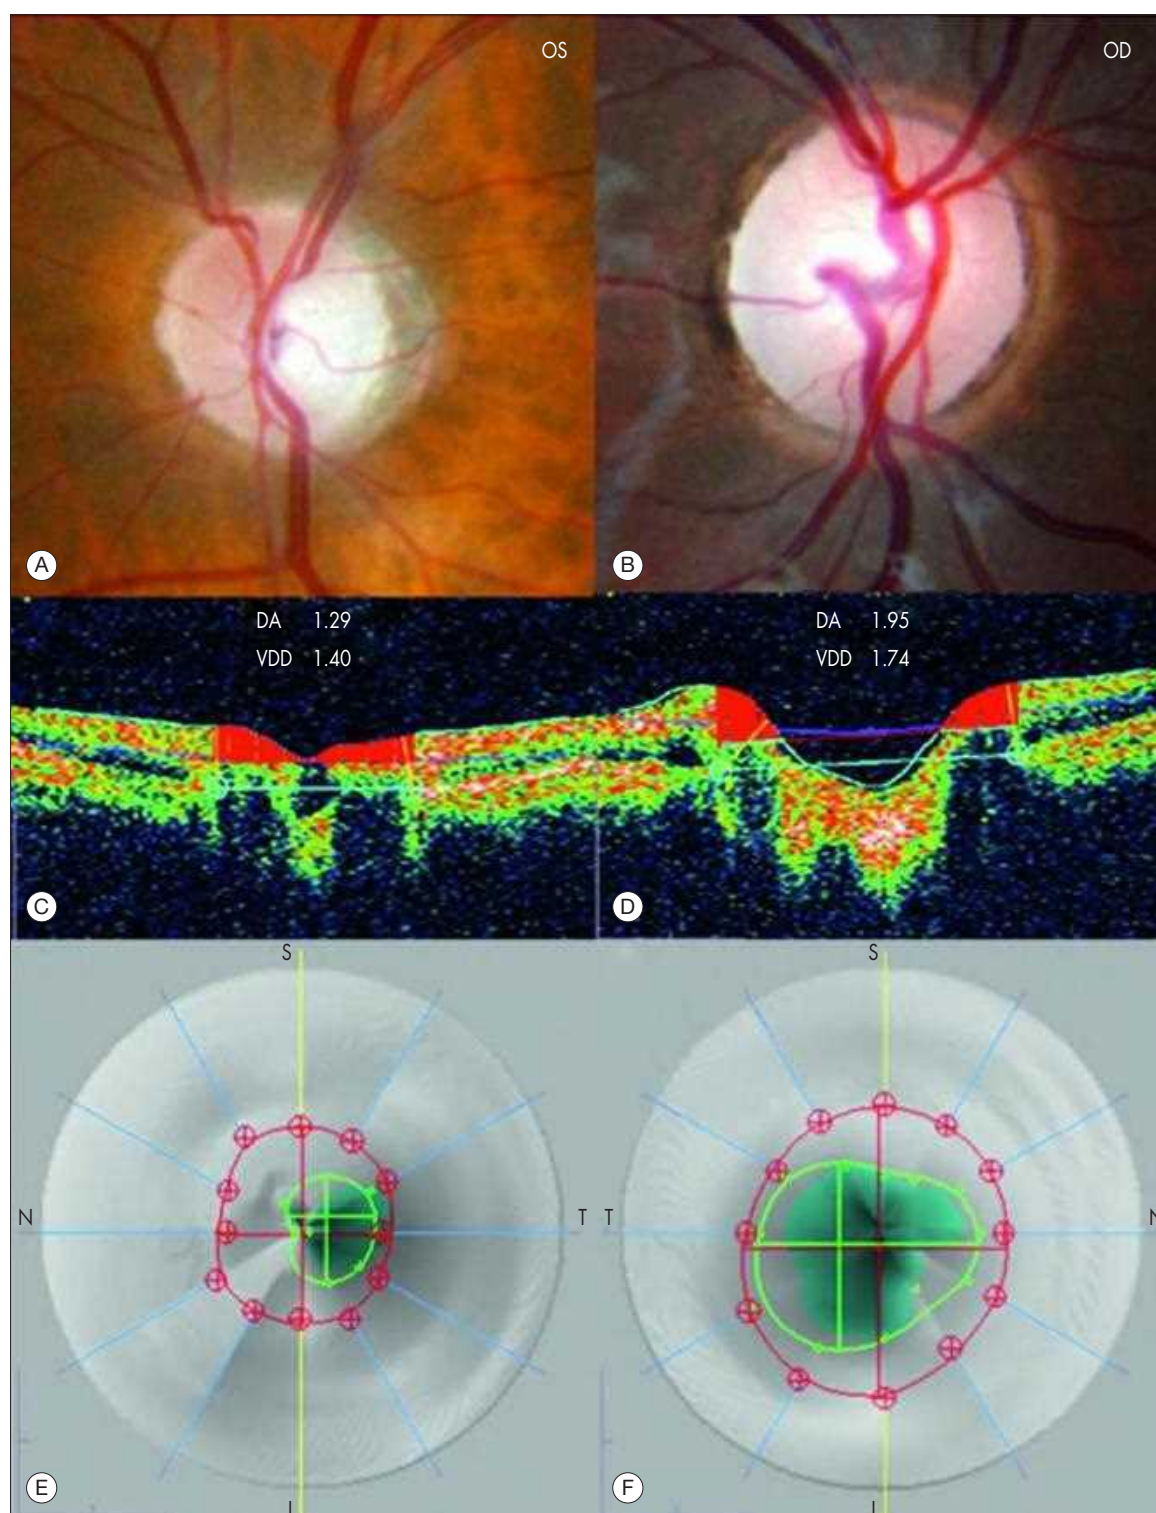

In early stages, mitochondria accumulate within retinal ganglion cells, which leads to RNFL thickening detectable by OCT.<sup>101</sup> If toxic drugs are not discontinued, peripapillary RNFL thinning in the inferotemporal sector and GCL thinning in the nasal sectors (corresponding to the papillomacular bundle) can occur (see Fig. 9.2.10). Finally, diffuse RNFL and GCL thinning results in the late stages. OCT is very helpful for early diagnosis to remove the toxic drugs or to treat malnutrition.

## Optical Coherence Tomography Angiography

In recent years, a new promising OCT detection system has been introduced—optical coherence tomography angiography (OCTA). The OCTA is a functional extension of OCT that images ocular vessels by detecting motion contrast between consecutive scans. Different devices are available for this purpose using different methods to detect the image (speckle or intensity decorrelation, phase variance, etc.). OCTA can show separately the microvasculature in various vascular networks including the optic nerve head, the superficial retina capillaries, the deep retina capillaries, and choriocapillaries (Fig. 9.2.13). Moreover, some OCTA devices can quantify optic nerve head and peripapillary perfusion.<sup>102</sup> The continuous updating of the software makes the measurements more accurate and reliable.

With use of OCTA, a reduction of optic nerve head perfusion has been detected in DOA<sup>104</sup> and in patients affected by MS with a history of optic neuritis, but not in patients affected by MS without a history of optic neuritis.<sup>103</sup>

A study conducted in chronic NAION shows reduction of vessel density in the peripapillary retina and within the optic disc. Moreover, the severity of visual field defect and peripapillary RNFL thinning was significantly associated with the peripapillary vessel density reduction but not with vessel density within the optic disc.<sup>105</sup> OCTA studies in the next few years are expected to lead to new understanding in the pathophysiology of different optic nerve diseases.

**Fig. 9.2.12** Fundus Pictures and Optical Coherence Tomography (OCT) Analysis of Dominant Optic Atrophy (DOA) Patients With a Small Optic Disc (A,C,E) and DOA Patient With Normal Optic Disc Size (B,D,F). (From Barboni P, Carbonelli M, Savini G, et al. OPA1 mutations associated with dominant optic atrophy influence optic nerve head size. *Ophthalmology* 2010;117:1547–53.)

**Fig. 9.2.13** Visualization of the Optic Nerve Head and of the Peripapillary Retina by Optical Coherence Tomography Angiography (OCTA) in a Normal 40-Year-Old Man. Note the different segmentation and the different vascular visualization of the four layers: nerve head, vitreous, radial peripapillary capillaries (RPC), and choriocapillary.

# Anatomy and Physiology

Alfredo A. Sadun

## 9.3

**Definition:** The optic nerve, being a portion of the central nervous system, is really a tract and not a (peripheral) nerve. The 1.2 million axons that emanate from the retinal ganglion cells carry the name optic nerve until they partially decussate at the optic chiasm.

### Key Features

- The optic nerve consists of four portions: intraocular (the optic disc), intraorbital, intracanalicular, and intracranial.
- Myelination starts posterior to the lamina cribrosa.
- The intraorbital optic nerve has redundant length by at least 8 mm for protection during eye movement.
- The intracranial optic nerves join at the optic chiasm, which also makes them susceptible to compression by lesions in the cavernous sinus.
- Blood supply to the optic nerve head is derived from the circle of Zinn–Haller, which receives blood from choroidal vessels, short posterior ciliary arteries, and pial arterial network.

### HISTORICAL REVIEW

Aristotle described optic nerves as joining at the optic chiasm, so-called because it resembles the Greek letter  $\chi$  (chi). In about AD 150, Galen of Pergamon gave a more detailed description of the optic nerves as sensory in nature but incorrectly as hollow and continuous with the ventricular system. Little progress in the understanding of the visual pathways occurred between Galen and Gratiolet, 1700 years later. Using soft

orangewood sticks for blunt dissection, Gratiolet was able to follow the retinofugal projection to the pretectum as well as to confirm the main pathway to the lateral geniculate nucleus.<sup>1</sup>

### GENERAL ANATOMY

The optic nerve carries about 1.2 million axons that derive from the retinal ganglion cells and project to the eight primary visual nuclei (Fig. 9.3.1).<sup>2–4</sup> However, only the anterior part of this heavily myelinated tract is termed the optic nerve. The optic chiasm consists of the partial decussation; the optic tract is the posterior continuation of the same fiber tract to its termination.

The optic nerve is about 50 mm long and extends from the eye to the optic chiasm. It is often described as consisting of four portions (Fig. 9.3.2):

- Intraocular portion (the optic disc, 1 mm in anterior–posterior length).
- Intraorbital portion (about 25 mm long).
- Intracanalicular portion within the optic canal (about 9 mm long).
- Intracranial portion (about 16 mm long).

Three anatomical zones occur within the 1-mm long intraocular optic nerve (optic disc): anteriorly, the retinal or prelaminar zone; centrally, the choroidal or laminar zone; posteriorly, the scleral or retrolaminar zone.

Each zone contains different structures and elements of neuroectoderm and mesoderm.<sup>5,6</sup>

### CONSTITUENT ELEMENTS

#### Axons

Retinal ganglion cell axons course toward the optic nerve head as unmyelinated, retinal nerve fibers and later as myelinated optic nerve fibers. A

Fig. 9.3.1 Retinal Projections to the Eight Primary Nuclei, Showing Distribution of Higher Order Visual Processing.

## THE FOUR PORTIONS OF THE OPTIC NERVE

**Fig. 9.3.2 The Four Portions of the Optic Nerve.** The lengths are given.

topographical separation of fibers begins in the retina, continues in the optic nerve, and then becomes less precise near the optic chiasm.

The axons represent the anatomical substrate of the neural connection. Their membrane cable properties permit a regenerative signal to be transferred from the retina to the primary visual nuclei. This signal travels fastest in the axons of largest caliber and in those with the most myelin. Conduction velocities in large, myelinated fibers (about 20 m/second) are much faster than the velocities in small, unmyelinated fibers (about 1 m/second) in the retina.<sup>7</sup>

This optic nerve-mediated signal is coded spatially (the axons are retinotopically distributed in the brain) and probably temporally (axonal firing frequency carries information).

In addition to the neural signals, axons permit the transfer of intracellular chemicals and organelles such as mitochondria from the neuron soma to the distal terminal and vice versa. Orthograde (proceeds from eye to brain) axoplasmic transport has a slow component that progresses at 0.5–3.0 mm/day and a rapid component that moves at 200–1000 mm/day.<sup>8,9</sup> Retrograde (brain to eye) axonal transport also occurs at an intermediate rate.

Most of the retinal ganglion cells are relatively small, concentrated in the macula, and contribute axons of small caliber that project to the parvocellular layers of the dorsal lateral geniculate nucleus (the so-called P cell system). P cells have color-opponent physiology and are thought to subserve high-contrast, high-spatial-frequency resolution. In contradistinction, M cells are larger cells that contain large, fast-conducting axons and make up about 5%–10% of the retinal ganglion cells. The M cells may be involved primarily with noncolor information of high-temporal and low-spatial frequency.<sup>10</sup>

Melanopsin retinal ganglion cells (mRGCs) belong to a newly discovered class of photoreceptor RGCs that subserve the autonomic functions including pupils and circadian rhythms.<sup>11,12</sup> mRGCs are intrinsically photoreceptive but also part of the retinal circuitry for nonimage-forming functions.<sup>11</sup> They may be selectively sensitive or robust to different retinal and optic nerve diseases.<sup>12</sup>

## Glia

Oligodendrocytes are specialized glia that provide membranes for axonal myelination. Myelination begins centrally during development and stops

at the lamina cribrosa of the optic disc at birth. However, oligodendrocytes may extend anomalously anterior to the lamina to myelinate the peripapillary retinal nerve fiber layer (optic disc medullation) in about 1% of the general population. Microglia and macrophages are cells that derive from the immune system and can move readily into the central nervous system from the vascular beds. The apoptosis of retinal ganglion cells, which occurs during development and in various diseases, is probably modulated by these glial cells. Astrocytes have extensive neurofibrillary processes that spread among the nerve fibers. These specialized glial cells line the borders between axons and other tissues and form part of the blood–brain barrier. When axons are lost because of optic atrophy, astrocytes move and proliferate to fill the empty spaces.

## FOUR PORTIONS OF THE OPTIC NERVE

### Optic Disc

The optic nerve head is 1 mm deep in the anteroposterior direction and 1.5 mm (horizontally) by 1.8 mm (vertically) in diameter at the level of the retina.<sup>13</sup> The retinal ganglion axons make an orthogonal turn from the nerve fiber layer and pass through one of 200–300 holes that perforate the lamina cribrosa, the collagenous support of the optic disc.<sup>6</sup> These axons must pass from an area of higher tissue pressure (intraocular compartment) to a zone of lower pressure (retrobulbar space). The arterial supply shifts from the central retinal artery to branches of the ophthalmic artery. The axons become myelinated immediately posterior to the lamina cribrosa.

### Intraorbital Optic Nerve

This portion of the nerve (25 mm) exceeds the anteroposterior distance from the globe to the optic foramen by at least 8 mm. This redundancy of the sinuous optic nerve protects it and the eye during eye movements.

The optic nerve diameter increases from 3 mm just behind the globe to about 4 mm at the orbital apex.<sup>14</sup> Most of their increased caliber is due to connected tissue. Throughout its orbital course, the nerve is surrounded by dura, arachnoid, and pia mater (Fig. 9.3.3). The subarachnoid space is continuous with the intracranial subarachnoid space and carries cerebrospinal fluid.

The optic nerve substance consists of 400–600 fascicles, each of which contains about 2000 fibers. The fascicles are separated by connective tissue septa through which run the smaller blood vessels. The axons are heavily myelinated (Fig. 9.3.4) by oligodendrocytes.

### Intracanalicular Optic Nerve

The optic nerve's intracanalicular portion begins as it enters the optic canal through an opening in the lesser wing of the sphenoid bone at the apex of the orbit known as the optic foramen (see Fig. 9.3.2). The orbital canal opening is elliptic, with its widest diameter oriented vertically. The intracranial opening of the optic canal is also elliptic but with the horizontal width greater than the height.<sup>15</sup> The medial canal wall is the thinnest and most likely to fracture. Small lesions that arise within the optic canal may compress and significantly damage the optic nerve.

### Intracranial Optic Nerve

Once past the hard fold of dura above the intracranial opening of the canal, the intracranial optic nerve runs for 12–16 mm to reach the optic chiasm. The intracranial optic nerve is now about 4.5 mm in average diameter.

Above each nerve lie the gyri recti of the frontal lobes of the brain. On the lateral side of the optic nerve may lie the internal carotid artery. The ophthalmic artery arises from the carotid and lies to the lateral side and below the nerve within its dural sheath. The proximity of the cavernous sinus makes it possible for tumors to produce cranial nerve palsies in combination with an optic neuropathy.

## CIRCULATION OF THE OPTIC NERVE

The ophthalmic artery derives from the top of the internal carotid artery siphon where it joins up with and occupies an inferior position to the nerve in the optic canal. In the canal and orbit, the artery gives off several branches that feed the pial circulation. At 8–12 mm behind the globe, the ophthalmic artery passes through the nerve sheath and into the nerve, where it runs up to the optic disc; here it is renamed as the central retinal

**Fig. 9.3.3 Anterior Optic Nerve.** The sheath and the vascular supply to the intraocular and intraorbital portions are shown.

**Fig. 9.3.4 Axons in the Retrobulbar Optic Nerve.** This is an ultrastructural high-magnification view approximately 5 mm behind the globe. Note the heavily myelinated axons of various sizes. The smaller axons are 0.6–0.9  $\mu\text{m}$  in diameter and are probably of retinal ganglion cells of the P cell system. The larger axons are 1–2  $\mu\text{m}$  in diameter and may be part of the M cell system.

artery (see Fig. 9.3.3); this artery does not contribute directly to the circulation of the optic nerve head. Instead, blood flow to the optic nerve head derives from the circle of Zinn-Haller, which receives three major sources of blood<sup>16,17</sup>:

- Choroidal vessels.
- Four or five short posterior ciliary arteries.
- Small contribution from the pial arterial network.

# Differentiation of Optic Nerve From Macular Retinal Disease

## 9.4

Alfredo A. Sadun, Vivek R. Patel

**Definition:** Optic nerve disease involves injury to the retinal ganglion cells and the axons that constitute the optic nerve, whereas macular disease involves injury to the retina in the foveal and parafoveal areas.

### Key Features

- Optic nerve lesions generally produce an afferent pupillary defect and a severe dyschromatopsia.
- Macular lesions cause variable loss of central acuity and metamorphopsia.
- Brightness sense is reduced in optic nerve disease and augmented in macular disease.

### Diagnostic Features

- Optical coherence tomography (OCT) and multifocal electroretinography testing can reveal macular disease.
- Contrast sensitivity and visual evoked response testing may disclose optic nerve disease.

## INTRODUCTION

Optic neuropathies and maculopathies often have overlapping presentations. For example, optic neuritis and central serous retinopathy may both present in a young adult as acute, painless, monocular visual loss. The relative absence of fundus findings in patients with acute visual loss may make the correct diagnosis problematic. Impairment of vision secondary to optic nerve dysfunction may be an indication of intracranial pathology, often requiring neurosurgical intervention. Conversely, maculopathies may respond to local treatments<sup>1</sup> such as laser photocoagulation, photodynamic therapy, corticosteroids, or antivascular endothelial growth factor (antiVEGF) agents or surgery. These differences in management strategies underscore the need to make an early and accurate distinction between an optic neuropathy and a maculopathy.

Optic neuritis and nonarteritic anterior ischemic optic neuropathy are the most common forms of optic neuropathies in younger and older adults, respectively. Macular disease may localize to the inner or outer retina, and the most common form of macular disease is age-related macular degeneration.

## OCULAR FEATURES

Loss of visual acuity due to optic nerve disease is usually perceived as a sense of generalized dimness, patchy dark spots, or black curtains across the visual field.<sup>2</sup> Optic neuropathies may also produce a darkening or desaturation of colors and objects, which may appear to have reduced contrast to the point of becoming indistinguishable. Pain may be associated with certain optic neuropathies but is a distinctly unusual finding in maculopathies.

Patients who have maculopathies complain of metamorphopsia in the central visual field.<sup>3</sup> Micropsia is more common than macropsia. Patients may also experience slight photophobia (increased brightness sense) or glare, in contrast to the dimness perceived by optic neuropathy patients.

## DIAGNOSIS AND ANCILLARY TESTING

### History

Determining the tempo of disease is central to reaching an accurate diagnosis. Optic neuritis usually develops over hours to days, stabilizes, and then shows improvement in the ensuing weeks. Anterior ischemic optic neuropathy causes a sudden loss of vision usually with minimal progression or resolution thereafter.<sup>2</sup> Maculopathies, on the other hand, may be acute or insidious in onset.

### Physical Examination

Although quite variable, visual acuity is generally more severely affected in macular diseases than in diseases of the optic nerve. Measurement of the afferent pupillary response,<sup>4</sup> color vision, and brightness sense testing<sup>5</sup> are three tests that are particularly sensitive to impairments of the optic nerve and may be affected to an extent that is out of proportion to the observed reduction in visual acuity. Brightness sense may be estimated subjectively when the patient is asked which eye sees a light brighter or quantified using neutral density filters or spectacles composed of two pairs of cross-polarizing filters.<sup>5</sup>

Fundus examination may disclose optic disc swelling, but optic disc elevation itself does not produce significant impairment of visual function.<sup>6</sup> Optic atrophy is generally first visualized about 1 month after acute injury to the nerve. Optic neuropathies may produce diffuse dropout or segmental losses in the nerve fiber layer (NFL). Sectoral disc edema with flame-shaped hemorrhages (anterior ischemic optic neuropathy), lumps and bumps (optic disc drusen), pathological cupping (glaucoma), sectoral optic atrophy, and secondary optic atrophy are patterns of optic disc changes that indicate different types of optic nerve damage.

Serous neurosensory retinal or retinal pigment epithelium (RPE) detachments, retinal vascular abnormalities, and exudates may all be seen by direct or indirect ophthalmoscopy or by stereomicroscopy. The indications and clinical utility of optical coherence tomography (OCT) (see Chapter 9.2) is rapidly increasing, allowing precise anatomical localization and characterization of posterior pole pathologies. In addition, simultaneous imaging of the retinal NFL can help determine the presence or absence of concurrent optic nerve fiber atrophy.

### Ancillary Testing

Optic neuropathies may cause a variety of visual field defects, some of which are fairly specific to the underlying disease. For example, toxic or nutritional deficiency optic neuropathies usually cause centrocecal field defects, whereas diseases of the optic nerve head often produce arcuate or altitudinal field defects. The visual field defect of a maculopathy is almost invariably a central scotoma with a zone of metamorphopsia that surrounds it. Tangent visual field testing remains a very effective way of assessing the central 20° of visual field and makes the identification of a small central scotoma easily. Amsler chart testing provides a very sensitive assessment of the central 10° of visual field<sup>7</sup> and documents the presence or absence of metamorphopsia, a strong indicator of macular disease. Threshold Amsler chart testing is a method in which the Amsler grid is made very sensitive.<sup>8</sup> In this approach, the patient wears specialized glasses with cross-polarizers in front of both oculars, which are turned to reduce the patient's perception so that the Amsler chart is barely discerned or views a computer screen with variable contrast.<sup>9</sup>

In macular disease, a delay usually occurs in the recovery of visual pigments that are bleached by a bright light. Conversely, bright light has no effect on optic nerve conduction. Fundus fluorescein angiography and autofluorescence are very useful for the characterization of retinal diseases.

The visual evoked response is not very helpful in distinguishing optic nerve dysfunction from a variety of other diseases, which include refractive error, maculopathy, or even feigned visual loss.<sup>10</sup> Nevertheless, the test can be useful when a bilateral disease of the optic nerves exists or when documentation is desired for medicolegal purposes.

Another test that is used to discriminate between the two diseases is contrast sensitivity testing, which can be done at different spatial frequencies.<sup>11</sup> Patients who have optic neuropathies may have deficiencies in the middle to high spatial frequencies, whereas patients who have maculopathies usually have deficiencies only in the highest spatial frequencies.

# Congenital Optic Disc Anomalies

Michael C. Brodsky

## 9.5

**Definition:** Unusual configurations of the optic disc(s) present since birth.

### Key Feature

- Small, pale, or unusually shaped optic discs may reflect mere curiosities or significant anomalies associated with visual defects.

### Associated Feature

- Abnormalities of the surrounding retina (e.g., in morning glory syndrome), anterior segment (e.g., iris coloboma), face, or brain may occasionally be seen.

## INTRODUCTION

The principles outlined here apply to the evaluation and management of children who have congenital optic disc anomalies.<sup>1</sup>

### Age Association

Children who have bilateral optic disc anomalies generally present in infancy with poor vision and nystagmus; those who have unilateral optic disc anomalies generally present during the preschool years with sensory esotropia.

### Central Nervous System Malformations

Central nervous system malformations are common in patients who have malformed optic discs. Small discs are associated with a variety of malformations that involve the cerebral hemispheres, pituitary infundibulum, and midline intracranial structures (e.g., septum pellucidum, corpus callosum).

Optic discs of the morning glory configuration are associated with the transsphenoidal form of basal encephalocele, whereas optic discs with a colobomatous configuration are associated with systemic anomalies in a variety of coloboma syndromes.

## OPTIC NERVE HYPOPLASIA

Optic nerve hypoplasia is a congenital anomaly that represents a major cause of impaired vision in children.<sup>1</sup> Histologically, it is characterized by a subnormal number of optic nerve axons with normal mesodermal elements and glial supporting tissue.<sup>2</sup> The ophthalmoscopic appearance is that of a small, gray, or pale optic nerve head, which is often surrounded by a yellowish mottled peripapillary halo, flanked on either side by a ring of pigment (double-ring sign)<sup>2</sup> (Fig. 9.5.1). Visual acuity may range from 20/20 to no light perception.<sup>2</sup> Because visual acuity depends only on the degree of papillomacular nerve fiber bundle hypoplasia, it does not necessarily correlate with the overall size of the disc.<sup>1</sup>

The term septo-optic dysplasia (de Morsier syndrome) describes the constellation of optic nerve hypoplasia, absence of the septum pellucidum, and partial or complete agenesis of the corpus callosum.<sup>2</sup> MRI of the brain in optic nerve hypoplasia frequently shows coexistent cerebral hemispheric abnormalities (most often schizencephaly) and absence of the pituitary infundibulum with or without posterior pituitary ectopia.<sup>3</sup>

Fig. 9.5.1 Optic Nerve Hypoplasia (Note Double-Ring Sign).

The association of septo-optic dysplasia with pituitary hormone deficiencies warrants endocrinological evaluation in children who have both optic nerve hypoplasia and absence of the pituitary infundibulum on MRI. Growth hormone deficiency is most common, followed by deficiency of thyroid-stimulating hormone, corticotrophic hormone, and vasopressin. In infants who have septo-optic dysplasia, a history of neonatal jaundice suggests hypothyroidism and neonatal hypoglycemia indicates corticotropin deficiency. Children who have corticotropin deficiency are at risk of sudden death from hypoglycemia and shock during intercurrent illness; parents should be instructed to administer injectable parenteral corticosteroids at the onset of febrile illness.<sup>4</sup>

## MORNING GLORY DISC ANOMALY

The morning glory disc anomaly is a congenital excavation of the posterior globe that involves the optic disc.<sup>5</sup> In morning glory anomaly, the optic disc is enlarged, orange or pink in color, and either excavated or situated within a funnel-shaped area of excavation (Fig. 9.5.2).<sup>5</sup> A variably elevated annular zone surrounds the disc with irregular areas of pigmentation and depigmentation. A white tuft of glial tissue overlies the center of the disc. The retinal blood vessels appear increased in number, arise from the periphery of the disc, run an abnormally straight course over the peripapillary retina, and tend to branch at acute angles. It is often difficult to distinguish arteries from veins. The macula may be incorporated into the excavated defect (macular capture).<sup>5</sup> Although mistakenly referred to as a variant of optic disc coloboma, the morning glory disc anomaly is truly a distinct anomaly, as evidenced by its sporadic occurrence, its lack of association with iris or retinal colobomas, and its systemic associations.<sup>5</sup>

The morning glory disc anomaly is associated with transsphenoidal encephalocele<sup>1</sup> and with hypoplasia of the ipsilateral intracranial vasculature (which can be visualized by magnetic resonance angiography).<sup>5,6</sup> Children who have this occult basal encephalocele have characteristic facies, which consist of mild hypertelorism with a depressed nasal bridge, a midline notch in the upper lip, and sometimes a midline cleft in the soft palate. Respiratory symptoms of transsphenoidal encephalocele in infancy may include rhinorrhea, nasal obstruction, mouth breathing, or snoring. Most affected children have no overt intellectual or neurological deficits,

**Fig. 9.5.3 Optic Disc Coloboma.**

**Fig. 9.5.5 Optic Pit.** Herniation of retinal tissue through an enlarged scleral opening along one side of the optic nerve. (Courtesy Dr. JB Crawford, from Irvine AR, Crawford JB, Sullivan JH. The pathogenesis of retinal detachment with morning glory disc and optic pit. *Retina*. 1986;6:146–50.)

but panhypopituitarism is common. Patients who have morning glory discs are also at risk of acquired visual loss. Nonrhegmatogenous retinal detachments develop in approximately one-third of eyes with morning glory discs and usually involve the peripapillary retina.<sup>5</sup>

## OPTIC DISC COLOBOMA

In optic disc coloboma, the disc appears enlarged and incorporates a sharply demarcated, glistening white, bowl-shaped excavation (Fig. 9.5.3).<sup>7</sup> The inferior rim of the disc is thinner than the superior rim, which reflects the position of the embryonic fissure relative to the primitive epithelial papilla. The excavation may extend inferiorly to involve the adjacent choroid and retina, in which case microphthalmia is frequently present. In some instances, the entire disc is excavated, but the colobomatous nature of the defect can still be appreciated ophthalmoscopically because the excavation is deeper inferiorly. The excavation is contained within the colobomatous optic disc, as opposed to the morning glory disc anomaly, in which the disc falls within the excavation.<sup>7</sup> Visual acuity may be minimally or severely affected, depending upon the extent of the lesion. Although the optic disc area appears enlarged, optic disc coloboma is actually an inferior segmental form of optic nerve hypoplasia, because the only remaining neural tissue lies superiorly in a C-shaped or moon-shaped crescent (see Fig. 9.5.3).

Optic disc coloboma may arise sporadically or be inherited in an autosomal dominant fashion and may be accompanied by iris or retinochoroidal colobomas in the same or fellow eye. Often it is associated with systemic anomalies in a number of genetic syndromes (e.g., CHARGE [coloboma of the eye, heart anomaly, choanal atresia, retardation, and genital and ear anomalies] association, Walker-Warburg syndrome, Goltz focal dermal

hypoplasia, Goldenhar's syndrome, linear nevus sebaceous syndrome) but rarely is it associated with transsphenoidal encephalocele.<sup>1</sup>

## OPTIC PIT

An optic pit appears as round or oval, gray, white, or yellowish crater-like depression in the optic disc (Fig. 9.5.4).<sup>7</sup> Optic pits commonly involve the temporal optic disc but may be situated in any sector.<sup>8</sup> Temporal optic pits are often associated with adjacent peripapillary retinal pigment epithelium changes.<sup>8</sup> In unilateral cases, the involved disc is slightly larger than the normal disc.<sup>8</sup>

Visual field defects are variable and often correlate poorly with the location of the pit; the most common defect appears to be a paracentral arcuate scotoma connected to an enlarged blind spot. Acquired depressions in the optic disc that are indistinguishable from optic pits have been documented in eyes with normal-tension glaucoma.<sup>1</sup> Histologically, an optic pit is a herniation of rudimentary neuroectodermal tissue into a pocket-like depression within the nerve substance<sup>8</sup> (Fig. 9.5.5). Its pathogenesis is unknown.

Optic pits are not associated with brain malformations, and their discovery does not warrant neuroimaging. Approximately 45% of eyes with optic pits develop macular retinoschisis and/or serous retinal detachments.<sup>6</sup> Some serous retinal detachments associated with optic pits resolve spontaneously, but the visual prognosis remains poor.<sup>8</sup> The subretinal fluid most likely originates from the vitreous cavity and/or the subarachnoid space that surrounds the optic nerve. Lincoff et al.<sup>9</sup> demonstrated that fluid from the optic pit initially produces an inner layer retinal separation (retinoschisis) that overlies the posterior pole. An outer layer macular hole subsequently develops through which this intraretinal fluid communicates with the subretinal space to form a sensory macular detachment

**Fig. 9.5.6 Megalopapilla.**

**Fig. 9.5.7 Congenital Tilted Right Optic Disc.** Note the inferonasal retinochoroidal depigmentation. (Left optic disc is the mirror image.)

that gradually enlarges.<sup>9</sup> The recent finding that vitrectomy with induction of posterior vitreous detachment without gas tamponade or laser photocoagulation allows resolution of optic disc pit maculopathy suggests that primary vitreous traction is the trigger for the schisis cavity and that the perivascular space around the pit allows for the passage of fluid into the retina.<sup>10</sup>

## MEGALOPAPILLA

Megalopapilla is a generic term that connotes an abnormally large optic disc that lacks the inferior excavation of optic disc coloboma or the numerous anomalous features of the morning glory disc anomaly.<sup>1</sup> This condition is usually bilateral and often associated with a large cup-to-disc ratio. Patients who have megalopapilla are often suspected to have glaucoma. Unlike the situation in glaucoma, however, the optic cup is usually round or horizontally oval with no vertical notch or encroachment (Fig. 9.5.6). Visual acuity is generally normal in megalopapilla but may be mildly decreased in some cases. Visual fields are usually normal except for an enlarged blind spot, which enables the examiner to rule out low-tension glaucoma or a compressive lesion. Megalopapilla is only rarely associated with brain anomalies, and neuroimaging is not warranted unless midline facial anomalies are present.

## CONGENITAL TILTED DISC SYNDROME

Tilted disc syndrome is a nonhereditary bilateral condition in which the superotemporal optic disc is elevated and the inferonasal disc is displaced posteriorly, which results in an optic disc of oval appearance with its long axis obliquely orientated (Fig. 9.5.7).<sup>11</sup> This configuration is accompanied by situs inversus of the retinal vessels, congenital inferonasal conus, thinning of the inferonasal retinal pigment epithelium and choroid, and myopic astigmatism. These features presumably result from a generalized

**Fig. 9.5.8 Congenital Optic Disc Pigmentation.**

ectasia of the inferonasal fundus that involves the corresponding sector of the optic disc.

Familiarity with this condition is important, because affected patients may present with the suggestion of bitemporal hemianopias, which involve primarily the superotemporal quadrants. However, when observed carefully these field defects do not respect the vertical meridian (as do chiasmal lesions). Furthermore, large and small isopters are fairly normal, but medium-sized isopters are constricted selectively because of the ectasia of the midperipheral fundus. Repeated visual field tests after correcting for the myopic refractive error often eliminate the field defect, which confirms its refractive nature. In some cases, retinal sensitivity is decreased in the area of the ectasia, which causes the defect to persist despite refractive correction. Rare cases of the tilted disc syndrome have been documented in patients who have congenital suprasellar tumors; neuroimaging is therefore warranted when the associated bitemporal hemianopia respects the vertical meridian.<sup>11</sup>

## CONGENITAL OPTIC DISC PIGMENTATION

Congenital optic disc pigmentation is a condition in which melanin anterior to or within the lamina cribrosa imparts a gray appearance to the disc (Fig. 9.5.8). True congenital optic disc pigmentation is extremely rare. Congenital optic pigmentation is compatible with good visual acuity but may be associated with coexistent optic disc anomalies that decrease vision.<sup>12</sup>

Most cases of gray optic discs are not caused by congenital optic disc pigmentation.<sup>12</sup> For reasons that are understood poorly, optic discs of infants who have delayed visual maturation or albinism—and those of some normal neonates—have a diffuse gray tint when viewed ophthalmoscopically. In these disorders, the gray tint disappears within the first year of life without visible pigment migration.

## AICARDI SYNDROME

The major features of Aicardi syndrome are infantile spasms, agenesis of the corpus callosum, modified hypsarrhythmia on electroencephalography, and a characteristic optic disc appearance that consists of multiple depigmented chorioretinal lacunae clustered around the disc (Fig. 9.5.9).<sup>13</sup> Associated systemic anomalies include vertebral malformations (e.g., fused vertebrae, scoliosis, spina bifida) and costal malformations (e.g., absent ribs, fused or bifurcated ribs).<sup>13</sup> Severe mental retardation is almost invariable. The intriguing association between choroid plexus papilloma and Aicardi syndrome has been documented in numerous patients.<sup>1</sup> In addition to agenesis of the corpus callosum, neuroimaging abnormalities in Aicardi syndrome include cortical migration anomalies (pachygyria, polymicrogyria, cortical heterotopia) and central nervous system malformations (cerebral hemispheric asymmetry, Dandy-Walker syndrome, colpocephaly, midline arachnoid cysts).<sup>1</sup> The inheritance pattern of Aicardi syndrome is attributed to an X-linked mutational event that is lethal in males.<sup>1</sup>

**Fig. 9.5.9** Aicardi Syndrome.

# Papilledema and Raised Intracranial Pressure

Alfredo A. Sadun, Michelle Y. Wang

## 9.6

**Definition:** Optic disc edema, usually bilateral, which results from increased intracranial pressure.

### Key Features

- Blurring of the optic disc margins.
- Anterior extension of the nerve head.
- Venous congestion of arcuate and peripapillary vessels.
- Hyperemia of the optic nerve head.

### Associated Features

- Gross elevation of the optic nerve head.
- Engorged and dusky veins.
- Peripapillary splinter hemorrhages.
- Occasionally choroidal folds and retinal striae.

## INTRODUCTION

About 1.2 million axons converge at the optic disc to form the optic nerve. The optic nerve follows a 50-mm course as it extends from the back of the eye, travels through the orbit, passes through the optic canal, runs intracranially, and partially decussates to form the optic chiasm. Each axon must maintain active axonal transport in both the orthograde (eye to brain) and retrograde directions. The subarachnoid space of the brain is continuous with the optic nerve sheath. A wide variety of insults may lead to dysfunction or compression of the optic nerve, potentially resulting in a partial arrest of axoplasmic transport, manifested as optic disc edema. If the compression is caused by raised intracranial pressure, the condition is termed papilledema, thus carrying neurological and neurosurgical connotations. If the cause of the disc edema is not increased intracranial pressure, the term optic disc edema should be used. Long-standing or severe papilledema, in addition to reflecting intracranial pathology, also may result in bilateral optic nerve dysfunction.

## EPIDEMIOLOGY AND PATHOGENESIS

Patients may suffer from many of the features of intracranial tumors in the absence of any mass lesion. Tumors of the posterior fossa may cause obstruction of cerebrospinal fluid (CSF) flow between the ventricles, but most cases of increased intracranial pressure in adults arise from large hemispheric masses that produce a mass effect.

Pseudotumor cerebri (PTC), also termed idiopathic intracranial hypertension (IIH), requires that neuroimaging prove negative for mass lesions and obstruction of the ventricular system and that a lumbar puncture reveals a high opening pressure with normal fluid composition.

Among young adults, papilledema is more likely to be caused by IIH than real tumor. IIH may initially present only with headache, which tends to be worst when recumbent. There is usually an absence of any neurological signs other than visual loss. Most patients are obese young women of childbearing age, leading to a suggestion that female sex hormones and endocrine abnormalities play an important role in this disorder. IIH may be seen in association with certain drugs such as tetracycline, oral contraceptive pills, growth hormone, vitamin A, or corticosteroids (or more commonly, corticosteroid withdrawal).

One well-understood association is intracranial venous thrombosis, which may be due to trauma, otitis media with mastoiditis, connective tissue disease, or hypercoagulable states. Chronic respiratory insufficiency, renal syndrome, iron deficiency anemia, and obstructive sleep apnea also have been associated with IIH.<sup>1</sup> When there is an identifying etiology, the condition is considered as secondary intracranial hypertension. Like glaucoma, increased intracranial pressure can be consequent to an increased production of fluid or to a decrease in outflow facility. Many investigators feel that most causes of IIH involve increased resistance to CSF drainage. Obstruction of the ventricular system or shunt failure may lead to a very rapid rise in intracranial pressure and fulminant papilledema.<sup>2</sup>

The principal pathophysiology of optic disc swelling is blockage of axoplasmic transport. Mechanical and vascular causes can combine to produce a blockage of optic nerve axoplasmic flow. Such blockage at the level of the lamina choroidalis and lamina scleralis occurs when optic disc edema is produced experimentally through increased intracranial pressure, ocular hypotony, or increased intraocular pressure. Optic disc edema also may be produced by an event that increases venous pressure at or near the lamina cribrosa,<sup>3,4,5</sup> such as occurs secondary to intrinsic tumors or extrinsic orbital masses or by abnormalities in blood flow such as central retinal vein occlusion (CRVO).

## OCULAR MANIFESTATIONS

It is useful to characterize the changes in the optic nerve head that occur in papilledema as being mechanical or vascular in nature.

The five mechanical clinical signs of optic disc edema are:

- Blurring of the optic disc margins.
- Filling in of the optic disc cup.
- Anterior extension of the nerve head (3 diopters = 1 mm of elevation).
- Edema of the nerve fiber layer.
- Retinal or choroidal folds or both.

The five vascular clinical signs of optic disc edema are:

- Venous congestion of arcuate and peripapillary vessels.
- Papillary and retinal peripapillary hemorrhages.
- Nerve fiber layer infarcts (cotton-wool spots).
- Hyperemia of the optic nerve head.
- Hard exudates of the optic disc.

In addition, elements of optic disc swelling can be used to help characterize the papilledema as early, fully developed, chronic, or late. Disc hyperemia, disc swelling, blurring of the disc margins, and blurring of the nerve fiber layer are found in early papilledema (Fig. 9.6.1). In fully developed papilledema, gross elevation of the optic nerve head and engorged and dusky veins appear, peripapillary splinter hemorrhages and sometimes choroidal folds arise, and retina striae are seen (Fig. 9.6.2). In chronic papilledema, fewer hemorrhages occur, the optic disc cup is obliterated completely, less disc hyperemia is seen, and hard exudates occur within the nerve head (Fig. 9.6.3). In late disc edema, secondary optic atrophy occurs, disc swelling subsides, retinal arterioles are narrowed or sheathed, and the optic disc appears dirty gray and blurred, secondary to gliosis (Fig. 9.6.4).

The Modified Frisén Scale was designed to help further quantitate papilledema<sup>6</sup>:

Grade 1 papilledema is characterized by a C-shaped halo with a temporal gap.

**Fig. 9.6.1 Early Papilledema.** The optic disc of an 18-year-old man 2 weeks after he had complained of diplopia arising from sixth cranial nerve palsies caused by increased intracranial pressure. Note the evidence of only mild edema.

**Fig. 9.6.4 Secondary Optic Atrophy From Chronic Papilledema.** The same 27-year-old obese female patient 5 months later. Note the secondary optic atrophy has developed fully. The disc margins appear hazy or "dirty."

**Fig. 9.6.2 Developed Papilledema.** The optic disc of a 36-year-old woman who suffered headache and blurred vision for 2 months. Fully developed disc edema present—note the engorged veins and peripapillary hemorrhages.

**Fig. 9.6.3 Chronic Papilledema.** Severe and chronic disc edema in a 27-year-old, very obese woman who has pseudotumor cerebri. Note that the disc cup is obliterated and hard exudates are present.

Grade 2 papilledema is characterized by circumferential halo.

Grade 3 papilledema is characterized by obscuration of one or more major blood vessels leaving the disc.

Grade 4 papilledema is characterized by obscuration of major vessels on the disc.

Grade 5 papilledema is characterized by obscuration of all vessels on and leaving the disc.

The most common symptoms as reported by the Idiopathic Intracranial Hypertension Study Group are headache, followed by, in decreasing frequency, transient visual obscuration, back pain, pulsatile tinnitus, and visual loss.<sup>7</sup>

The headache of increased intracranial pressure usually is quite distinctive. When elevated intracranial pressure is marked, the headache is particularly severe or associated with nausea and vomiting or a sense of pressure around the ears. Further symptoms of more advanced elevated intracranial pressure include worsening of the headache in a recumbent position and in the early morning, with improvement during the day. More specific complaints are the transient obscurations of vision, usually described as monocular or binocular blackouts, which last 3 to 4 seconds and most often occur as the patient arises from the recumbent position to sitting or standing.<sup>8</sup> Papilledema may produce visual blurring because of enlargement of the blind spot or retinal edema; this blurring usually is reversible. However, further injury to the optic nerve may be associated with secondary optic atrophy and be permanent, which results in symptoms such as constricted visual fields and later poor color vision and poor visual acuity. Diplopia usually arises from nonlocalizing sixth cranial nerve palsies, and it often resolves after the increased intracranial pressure has been controlled. The headache of raised intracranial pressure should be carefully distinguished from secondary headaches in IIH. Friedman and Rausch reported that the majority of IIH patients may suffer from chronic tension-type, migraine, or cluster headaches long after intracranial pressure has normalized.<sup>9</sup>

## DIAGNOSIS AND TESTING

Suspicion for papilledema is provided by the history. Careful fundus examination is mandatory. The optic nerve head is assessed for each of the 10 signs of disc edema described earlier and the papilledema characterized also as early, developed, late, or chronic. To determine whether the disc edema is, in fact, papilledema, neuroimaging is followed by a lumbar puncture with manometry. Automated visual fields such as Humphrey (HVF) are most important in assessing visual status. This is key to quantifying changes and monitoring response to treatment. HVF is as critical in the management of IIH as for the management of glaucoma.

In IIH, the most common visual field loss is arcuate defect with an enlarged blind spot. Optical coherence tomography (OCT) may be a helpful tool to quantitate the extent of papilledema, especially for lower grades (see Chapter 9.2). The diagnostic criteria were first introduced by

Dandy in 1937, which were later modified in 1985<sup>10</sup>: IIH patients must exhibit signs and symptoms of elevated intracranial pressure (confirmed by opening pressure measurement) without localizing neurological signs, abnormal CSF composition, or structural abnormalities on neuroimaging.

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis of papilledema is disc edema without increased intracranial pressure and pseudopapilledema. The latter rubric includes all abnormalities of the optic disc that can mimic optic disc edema. The most common of such disc anomalies are optic disc drusen, which, especially when deeply buried, may give the disc a lumpy, elevated appearance. Other causes of optic disc edema without increased intracranial pressure need to be considered—compressive optic neuropathies, papillitis, anterior ischemic optic neuropathy, CRVO, juvenile diabetic papillopathy, and optic disc vasculitis.

### Compressive Optic Neuropathies

Compressive optic neuropathies that may produce disc edema often are due to lesions located in the anterior orbit. Neoplasms of the optic nerve itself (gliomas) or of its sheaths (meningiomas) or masses from the orbital tissues or paranasal sinuses may impinge on the anterior optic nerve and result in disc edema. Inflammatory and infiltrative lesions also may manifest as masses. Distal malignancies may involve the optic nerve and its sheaths by metastasis.

### Papillitis

Papillitis often has a component of disc edema and may follow a prodromal viral illness. The inflammation may extend beyond the confines of the optic disc as a neuroretinitis. Cells are found in the vitreous humor; retinal exudates may form a macular star or a half-star figure. Both papillitis and neuroretinitis are seen often in young, healthy adults.

### Anterior Ischemic Optic Neuropathy

Anterior ischemic optic neuropathy usually presents as disc edema with peripapillary hemorrhages. An acute loss of vision is noted, and the visual field deficit may take on an altitudinal shape. Anterior ischemic optic neuropathy is found most often in patients age 50 to 75 years who have hypertension, diabetes, hyperlipidemia, or obstructive sleep apnea.<sup>11</sup>

### Central Retinal Vein Occlusion

CRVO may result in congestion in the optic nerve heads. However, the retinal hemorrhages and venous tortuosity in all four quadrants found in CRVO usually make the differentiation easy. Generally, CRVO occurs in middle-aged or older individuals who have hypertension or, less often, hyperviscosity syndrome. CRVO is typically unilateral.

### Diabetic Papillopathy

Diabetic papillopathy may present with unilateral or bilateral disc edema. Visual loss is usually minimal. The fundus examination often reveals dilated telangiectatic vessels over the discs, which disappear when the disc edema resolves spontaneously 4 to 8 weeks later.

### Optic Disc Vasculitis

Optic disc vasculitis (papillophlebitis), or posterior segment uveitis, also may result in optic disc edema. Papillophlebitis, optic disc vasculitis, benign retinal vasculitis, and “the big blind spot syndrome” may be considered variations on this theme. These conditions often develop in young, healthy adults who have only minimal visual impairment. The optic disc edema usually occurs in association with engorged retinal veins. If a cilioretinal artery is present, it may be obstructed. This condition is rarely bilateral.

### Other Causes

Other causes of disc edema include advanced Graves’ disease, malignant hypertension, and hypotony. Malignant processes such as carcinoma,

lymphoma, or leukemia as well as uremia<sup>12</sup> and sarcoid granuloma also may cause swelling of the optic disc. Nutritional optic neuropathies such as in tropical epidemics and toxic optic neuropathies often caused by drugs such as ethambutol may rarely result in mild disc edema.<sup>13</sup> Orbital or cranial trauma, radiation, and burns also may cause swelling of the optic discs.

## SYSTEMIC ASSOCIATIONS

In addition to papilledema and the potential for visual loss, increased intracranial pressure can cause other signs and symptoms. However, the most serious and irreversible problems associated with increased intracranial pressure per se are visual, hence the ophthalmologist is a critical member of the clinical team for such patients. Palsies of the sixth cranial nerve, hearing loss, and facial nerve palsies also are found, in decreasing order of frequency, in patients who have increased intracranial pressure. However, these cranial nerve palsies are likely to be self-limiting after reduction of the pressure.

## PATHOLOGY

The histopathology of acute optic disc edema reveals axoplasmic stasis, edema, and vascular congestion (Fig. 9.6.5). Peripapillary hemorrhages are seen primarily in the retinal nerve fiber layer, but they may overlie the optic disc. The increase in tissue mass fills the physiological cup and causes the optic nerve head to protrude anteriorly. The small blood vessels are engorged and tortuous. Vacuoles of extracellular fluid accumulate in and anterior to the retinal lamina cribrosa, and the subarachnoid space is enlarged with stretching of the subarachnoid strands.

The neural retina is displaced away from the optic disc, and the outer layer of the retina may be buckled (retinal folds). The rods and cones are displaced away obliquely from their anchor near Bruch’s membrane. A shallow retinal detachment in the peripapillary area probably accounts for most of the enlarged blind spot.

Engorgement of axons in the laminar portion of the optic nerve is demonstrated by electron microscopy. The swollen axons are filled with mitochondria primarily anterior to the choroidal lamina cribrosa. The mitochondria and the fascicles of microtubules are in disarray. Importantly, the extracellular accumulation is minimal compared with the intracellular and intra-axonal accumulation.<sup>14</sup>

## TREATMENT

The treatment of papilledema associated with visual loss depends in large part on the cause, symptoms, signs, and progression of the problem. Attempts must be made to address the pathophysiology, but a few comments on the general concepts are provided. Treating the cause of high intracranial pressure and lowering the pressure should occur in parallel.

Medical treatment usually consists of diuretics, especially carbonic anhydrase inhibitors such as acetazolamide and, in cases of IIH, weight reduction.<sup>15</sup> Serial lumbar punctures can at least buy time. If medical treatment is not sufficient, surgical approaches such as optic nerve sheath decompression<sup>16,17</sup> or a ventriculo- or lumboperitoneal shunt<sup>18</sup> may need to be carried out. It is very important to understand that the decision to treat or to alter treatment modality usually is based on the ophthalmologist’s descriptions of the extent of both signs and symptoms and most especially visual loss as measured by visual fields. Hence the ophthalmologist is a crucial member of the clinical team that makes management decisions.

## COURSE AND OUTCOME

The prognosis for papilledema is largely dependent on the cause. Most patients who have metastatic brain tumors do very badly; those who have ventricular obstructive disease may be shunted successfully; patients who have IIH usually can be managed well.

Two general points warrant emphasis. The diagnosis of papilledema requires a prompt workup until the most serious pathologies are ruled out. Here, neurological, neurosurgical, or neuroradiological consultations may be required. However, once the problem has been reduced to that of papilledema, the ophthalmologist can best determine how aggressive the course of management needs to be. All too often, permanent visual loss occurs in diseases such as IIH for lack of appropriate and timely ophthalmological involvement.

**Fig. 9.6.5 Optic Disc Edema.** (A–B) Patient has bilateral optic disc edema secondary to grade IV malignant hypertension. Note exudates in nasal macula (B). (C) Histological section shows optic disc edema secondary to ocular hypertension caused by phacolytic glaucoma. (D) Optic disc edema secondary to ocular hypotony caused by a ruptured globe. Optic disc edema can be caused by increased intracranial pressure or increased or decreased intraocular pressure. The main finding in C and D consists of increased mass of anterior optic nerve caused by axonal swelling, optic nerve head tissue edema and vascular congestion, and lateral displacement of photoreceptors from the end of Bruch's membrane, which terminates in a ring at the optic nerve.

# Inflammatory Optic Neuropathies and Neuroretinitis

## 9.7

Heather E. Moss, Jason R. Guercio, Laura J. Balcer

**Definition:** Inflammation of the optic nerve may spare the optic disc (retrobulbar optic neuritis) or may cause optic disc swelling (papillitis). The term optic neuritis is typically reserved for optic nerve inflammation that may be associated with demyelinating disease. Inflammation of the optic disc with adjacent retinal exudation is referred to as neuroretinitis.

## Key Features

- Abrupt and progressive vision loss.
- Dyschromatopsia.
- Afferent pupillary defect in unilateral cases.

## Associated Feature

- Pain, particularly on eye movement.

## INTRODUCTION

Primary inflammation of the optic nerve is referred to as papillitis when the optic disc is swollen and retrobulbar neuritis when the disc appears normal. The most common form of optic nerve inflammation is acute demyelinating optic neuritis. Much of our current knowledge about acute demyelinating optic neuritis derives from the Optic Neuritis Treatment Trial (ONTT). The ONTT was a multicenter trial supported by the National Eye Institute, which assessed the benefit of corticosteroid treatment for optic neuritis and investigated the relationship between optic neuritis and multiple sclerosis (MS).<sup>1-16</sup> Although numerous systemic inflammatory and autoimmune conditions are associated with acute or chronic optic nerve inflammation, this chapter focuses on acute demyelinating optic neuritis.

## EPIDEMIOLOGY AND PATHOGENESIS

The annual incidence of optic neuritis, as estimated in population-based studies, is between 3 and 5 per 100 000 per year,<sup>17</sup> whereas the prevalence is 115 per 100 000.<sup>18</sup> The majority of patients who develop optic neuritis are between the ages of 20 and 50 years. Women are affected more commonly than men. In the ONTT, 77% of the patients were women, 85% were white, and the mean age was  $32 \pm 7$  years. In most cases, the pathogenesis of optic neuritis is inflammatory demyelination, regardless of whether MS is diagnosed clinically.<sup>19-20</sup> It is likely that many cases of monosymptomatic optic neuritis occur as the initial manifestation of MS.<sup>21</sup> A minority of cases are the initial manifestation of neuromyelitis optica, a demyelinating disease now recognized as distinct from MS, particularly with regard to natural history and treatment.

## OCULAR MANIFESTATIONS

Loss of vision in patients with acute demyelinating optic neuritis is usually abrupt and progressive, occurring over several hours to days. Progression for more than one week or failure of recovery to begin within four weeks is possible but should suggest a search for an alternative underlying cause.<sup>22-27</sup> Vision loss is usually monocular, although occasionally both eyes are affected simultaneously, particularly in children and in association with neuromyelitis optica.

Mild pain in or around the eye is present in more than 90% of patients. Such pain may precede or occur concomitantly with visual loss, is usually exacerbated by eye movement, and generally lasts no more than a few days. The presence of pain, particularly on eye movement, is a helpful (although not definitive) clinical feature that differentiates acute demyelinating optic neuritis from nonarteritic anterior ischemic optic neuropathy (NAION).<sup>28</sup>

On examination, optic nerve dysfunction is evident. The severity of visual loss varies from a mild visual field defect to severe loss of central acuity (3% of ONTT participants had no light perception, and in 90% there was at least some loss of central acuity).<sup>3</sup> Severe loss of visual acuity is more common in children.<sup>29</sup> Color vision and contrast sensitivity are impaired in almost all cases, often out of proportion to visual acuity. Visual field loss, which may be diffuse (48%) or focal (i.e., nerve fiber bundle defects, central or cecocentral scotomas, hemianopic defects), is also common in acute optic neuritis.<sup>4</sup> Altitudinal defects (focal visual field loss above or below the horizontal meridian) are less common and should prompt consideration of a diagnosis of AION.<sup>29</sup> Low-contrast letter acuity has recently emerged as a very sensitive test for optic neuropathy.<sup>30</sup> A relative afferent pupillary defect (rAPD) is detected in almost all unilateral cases of optic neuritis. If an rAPD is not present, a pre-existing or coexisting optic neuropathy in the fellow eye must be suspected. In fact, asymptomatic visual dysfunction is fairly common among fellow eyes of patients who have apparent unilateral optic neuritis.<sup>7</sup>

The optic disc appears normal in approximately two-thirds of adults with acute demyelinating optic neuritis (retrobulbar optic neuritis), whereas disc swelling is present in about one-third of adult cases (papillitis) (Fig. 9.7.1). Children with optic neuritis experience optic disc swelling more frequently than do adults.<sup>29</sup> Funduscopic features of optic disc swelling include elevation of the optic nerve head, disc hyperemia, blurring of the disc margins, and edema of the nerve fiber layer.<sup>31</sup> Optic disc hemorrhages were uncommon in the ONTT (6%), and their presence should suggest an alternative diagnosis.

Fig. 9.7.1 Optic Disc Swelling (Papillitis) Associated With Acute Optic Neuritis.

**BOX 9.7.1 Differential Diagnosis of Acute Unilateral Optic Neuropathy****Anterior Ischemic Optic Neuropathy**

Tumor  
 Aneurysm  
 Vasculitis  
 Neuroretinitis  
 Metastatic carcinoma  
 Lymphoreticular disorder  
 Sinusitis  
 Granulomatous inflammation  
 Leber's hereditary optic neuropathy (although always bilateral, this frequently presents initially with visual loss in only one eye)

**DIAGNOSIS AND ANCILLARY TESTING**

The diagnosis of acute demyelinating optic neuritis is based on an appropriate history (typical versus atypical course) and clinical signs and symptoms as described above. Diagnostic tests, including magnetic resonance imaging (MRI), cerebrospinal fluid (CSF) analysis, and serological studies, usually are performed for the following reasons<sup>10–11,16</sup>:

- In atypical cases, to determine if the cause is noninflammatory (such as a compressive lesion), or an inflammatory or infectious process.
- In typical monosymptomatic cases, to determine the prognosis or risk for subsequent development of MS.

In patients with suspected optic neuritis, MRI of the brain and orbits with fat suppression and gadolinium should be performed, even in typical cases, to confirm the diagnosis and to assess for the presence of other white matter lesions, which may be diagnostic of MS or place the patient in a high-risk category for development of MS.<sup>10–11,16</sup> Optical coherence tomography (OCT) is not altered in the acute phase other than distortion caused by papillitis, although abnormalities developing months after symptom onset may be useful in predicting the subset of optic neuritis patients who will suffer persistent visual dysfunction. A 2006 study of 54 patients documented a poor visual outcome in patients with a retinal nerve fiber layer (RNFL) thickness of less than 75  $\mu\text{m}$  measured with OCT within 3 to 6 months of an initial optic neuritis event.<sup>32</sup>

**DIFFERENTIAL DIAGNOSIS**

The diagnosis of acute visual loss begins with the localization of the involved portion of the visual system. A unilateral optic neuropathy is presumed when no ocular cause for visual loss is apparent and an rAPD is present with or without abnormal appearance of the optic nerve head. The differential diagnosis for acute optic neuropathy is outlined in [Box 9.7.1](#). Because most cases of optic neuritis produce unilateral visual loss, discussion here is limited to unilateral optic neuropathies. When there is acute visual loss and unilateral optic disc swelling, both optic neuritis and AION must be considered. Although the clinical profiles of these disorders overlap, AION is typically painless, occurs in patients over 50 years of age, and may be associated with optic disc hemorrhages. When the optic disc is normal in patients with unilateral optic neuropathy, a compressive lesion must be excluded; this usually is differentiated from acute optic neuritis by a history of progressive visual loss beyond the typical period of 1 to 2 weeks.

Other inflammatory, infectious, and neoplastic disorders may produce infiltration or demyelination—or both—of the optic nerve. These conditions may appear as either acute or progressive visual loss, and include sarcoidosis, systemic lupus erythematosus (SLE), syphilis, postviral syndromes, lymphoma, and leukemia. The treatment of optic neuritis in the setting of such systemic disorders is dictated by guidelines for appropriate treatment of the underlying infectious, inflammatory, or autoimmune disorder itself.<sup>31</sup>

Neuroretinitis, characterized by optic disc edema with macular hard exudates (macular “star”), must be differentiated from acute demyelinating optic neuritis ([Fig. 9.7.2](#)). Macular edema is initially diffuse; hard exudates form within days, frequently in a star-shaped pattern. Deep, whitish lesions may be noted at the level of the retinal pigment epithelium scattered throughout the fundus. Most cases of neuroretinitis are idiopathic, but the diagnosis requires the exclusion of infectious causes such as *Bartonella*

**Fig. 9.7.2 Optic Disc Edema and Macular Star Formation.** Color fundus photograph from a 13-year-old girl who came to medical attention with counting fingers acuity secondary to cat scratch neuroretinitis.

*henselae* (cat scratch disease), *Toxoplasma gondii* (toxoplasmosis), *Treponema pallidum* (syphilis), *Toxocara canis* (toxocariasis), *Borrelia burgdorferi* (Lyme disease), leptospira spp. (leptospirosis), *Mycobacterium tuberculosis* (tuberculosis), *Histoplasma capsulatum* (histoplasmosis), *Rickettsia typhi* (murine typhus), and brucella spp. (brucellosis). Nonspecific viral syndromes and viral etiologies involving Epstein-Barr virus (EBV), herpes simplex virus (HSV), human immunodeficiency virus (HIV), mumps, or hepatitis B or C have also been implicated.<sup>33</sup>

**Viral and Postviral Syndromes**

Parainfectious optic nerve inflammation typically follows the onset of a viral infection by 1–3 weeks, but it also can occur as a postvaccination phenomenon. It is more common in children than adults and likely occurs by an immunological process that produces optic nerve demyelination. Postviral (or parainfectious) optic neuritis may be unilateral but is frequently bilateral. The optic discs may appear normal or swollen; retinal involvement (neuroretinitis) is common when there is optic disc swelling. Associated meningoencephalitis, with MRI changes and CSF pleocytosis, is not unusual. Visual recovery after parainfectious optic neuropathy usually is excellent, even with no treatment. Corticosteroids may or may not hasten recovery, but this treatment is reasonable to consider, particularly in cases of bilateral, severe visual loss.

**Sarcoidosis**

Granulomatous inflammation of the optic nerve is a frequent ocular manifestation of sarcoidosis and may be an initial sign of this disorder. Clinical findings may be similar to those of acute demyelinating optic neuritis. However, the optic disc may have a characteristic lumpy, white appearance, suggestive of granulomatous infiltration. Recovery of vision is rapid in most cases following corticosteroid treatment. In fact, rapid recovery of vision with corticosteroid treatment and subsequent deterioration following taper is atypical for acute demyelinating optic neuritis and should suggest an infiltrative process such as sarcoidosis. Neuroretinitis is an uncommon intraocular finding in sarcoidosis.<sup>34</sup>

**Syphilis**

Syphilitic optic neuritis has become more common since the increase in prevalence of human HIV infection (see later). Optic nerve involvement may be unilateral or bilateral. Vitreous cellular reaction is a feature of

syphilis not seen in acute demyelinating optic neuritis. The diagnosis is established with identification of positive syphilis serological and CSF VDRL (Venereal Disease Research Laboratories) test results. Treatment with aqueous crystalline penicillin G, 18 to 24 million units per day, administered as 3 to 4 million units intravenously every 4 hours (or continuous infusion) for 14 days produces visual recovery in most cases, but recurrences are possible.<sup>35</sup> Secondary syphilis can also manifest as neuroretinitis with variable severity of visual loss.

## Lyme Disease

Although optic neuritis has been reported in patients with positive Lyme serological test (enzyme-linked immunosorbent assay [ELISA] and Western blot) results or other neurological findings suggestive of Lyme disease, definitive evidence of a causal relationship with *B. burgdorferi* infection has not been established in most cases.<sup>36–37</sup> However, patients with neurological or ocular manifestations should, in most cases, receive a 2- to 4-week course of intravenous ceftriaxone or alternative agent, with resolution of related symptoms within weeks.<sup>37–38</sup> Syphilis infection may produce false-positive Lyme disease serological examination results and therefore must also be considered in patients with optic neuropathy or other neurological manifestations.

## Cat Scratch Disease

*Bartonella henselae* is implicated in numerous ophthalmic disease states, including neuroretinitis. Prevalence of neuroretinitis in cat scratch disease (CSD) is documented to be between 1% and 2%. But as was shown in a 2000 retrospective study of patients who develop neuroretinitis, nearly two-thirds show serological evidence of past or present CSD infection (9 out of 14 tested patients, or 64%), suggesting that CSD may be the most common cause of neuroretinitis.<sup>39</sup> Patients with CSD ophthalmopathy show classic ophthalmoscopic signs of neuroretinitis, including diffuse disc edema, nerve fiber layer hemorrhages, cotton-wool spots, multiple discrete lesions in the deep retina, and stellate macular exudates (Fig. 9.7.2). Such patients have diminished visual acuities ranging from 20/25 to counting fingers. APDs, dyschromatopsia, and visual field abnormalities are common. CSD neuroretinitis may be unilateral or bilateral as well as asymptomatic and generally has a benign course with an excellent prognosis for visual recovery to 20/40 or better. A small subset of patients may experience a prolonged febrile illness and remain more severely impaired, with failure to regain baseline visual acuity.

Early therapy with oral doxycycline (for patients older than 8 years) or erythromycin (for younger patients) and rifampin for 4–6 weeks promotes resolution of CSD neuroretinitis and truncates the systemic infection, typically resulting in regression of posterior pole findings and the return of 20/20 visual acuity after 1–4 weeks of therapy. Long-term use of doxycycline or a macrolide may also be useful for preventing recurrences in HIV-positive patients.<sup>40–41</sup>

## Toxoplasmosis

Optic neuropathies are common in patients with *Toxoplasma gondii* infection, the most important protozoan cause of intraocular inflammation in the world, and include retinochoroiditis, papillitis, and neuroretinitis.<sup>42–43</sup> Ocular lesions primarily affect the retina, and the hallmark of the disease is focal necrotizing retinitis, ultimately resulting in characteristic atrophic scars. Active retinal lesions are oval or circular, with a cream-colored retina and surrounding retinal thickening due to necrosis and edema. Common symptoms include black floating spots, blurred vision, ocular pain, and redness, and if the visual axis or macula is involved, severely reduced vision. The disease is bilateral in 40% of cases, almost exclusively in the immunocompromised. It is usually a self-limiting disease in non-AIDS patients, and without treatment, inflammation gradually subsides and the lesions heal in 6–8 weeks.

## Optic Neuropathy in HIV Disease

In immunocompromised patients, particularly those with HIV infection, many infectious diseases may cause optic neuropathy, including tuberculosis, toxoplasmosis, toxocariasis, cytomegalovirus, herpes zoster, Cryptococcus, and other fungi. Primary central nervous system lymphoma infiltrating the optic nerves and chiasm has been reported recently in patients with HIV.<sup>44a</sup> Optic neuropathy may also be from HIV directly or from antivirals used to treat HIV.<sup>44b,c</sup>

## Systemic Lupus Erythematosus and Other Vasculitides

Optic neuropathy may occur in patients with SLE, polyarteritis nodosa, and other systemic vasculitides. Involvement of the optic nerve occurs in about 1% of patients who have SLE. Rarely, the disease manifests with optic neuropathy. The pathogenesis is related to ischemia, which may produce demyelination alone or in combination with axonal necrosis. Clinical manifestations may include those similar to acute optic neuritis (both papillitis and retrobulbar neuritis), acute ischemic optic neuropathy, or chronic progressive visual loss. The diagnosis of SLE as a cause of optic neuropathy is established by identification of systemic symptoms and signs of the disease and by serological testing. Treatment with high-dose corticosteroids is indicated and has been demonstrated to reverse severe visual loss.<sup>45</sup>

The term autoimmune optic neuritis has been suggested for cases of corticosteroid-responsive optic neuropathy with serological evidence of vasculitis (such as antinuclear antibodies, ANA) but no signs of systemic involvement.<sup>46</sup> However, the existence of “autoimmune optic neuritis,” distinct from either SLE or MS, is unproved. Patients with acute demyelinating optic neuritis or MS also may have positive ANA serological test results. Among ONTT participants, the ANA finding was positive at a titer less than 1:320 in 13% and greater than 1:320 in 3%. Only one patient developed a diagnosable connective tissue disease during the first 2 years of follow-up. Visual outcomes for these patients were similar between the placebo and intravenous methylprednisolone groups.

## Neuromyelitis Optica

Neuromyelitis optica (NMO), also known as Devic’s disease, is the association of unilateral or bilateral optic neuritis with longitudinally extensive transverse myelitis lesions and other typical clinical syndromes. It is currently thought of as a distinct entity from MS.<sup>47</sup> Recent work has identified aquaporin-4 antibody (AQP4-IgG) as a serological test that helps to differentiate cases of NMO from typical MS and may help identify monosymptomatic patients who are at risk of developing NMO.<sup>48</sup> Aquaporin-4 is a protein centered around astrocytic foot processes in the blood–brain barrier.<sup>48</sup> The pathology consists of vasculocentric inflammation with deposition of complement that results in necrotic lesions within the optic nerve and spinal cord. Revised NMO spectrum disorder diagnostic criteria were published in 2015 and include criteria for patients with and without detectable levels of AQP4-IgG.<sup>49</sup> Monosymptomatic patients with AQP4-IgG in their serum can be diagnosed with NMO spectrum disorder based on these criteria. The prognosis for functional recovery is worse than multiple sclerosis given the destructive nature of the lesions. It may be monophasic or recurrent. Recurrent disease has a much worse prognosis and higher mortality rate.<sup>50</sup> The treatment mainstay is high-dose corticosteroids and plasmapheresis for acute relapses including optic neuritis. Various immunosuppressive treatments have been used in NMO, including azathioprine (2–3 mg/kg daily), oral prednisone, and mycophenolate mofetil (1 gram twice daily).<sup>47</sup> More recently, rituximab, a monoclonal antibody drug that targets CD20+ cells, has been shown to be effective in NMO.<sup>51</sup>

## Association With Multiple Sclerosis

Although inflammation of the optic nerve occurs in numerous systemic disorders as outlined earlier, acute demyelinating optic neuritis occurs most often in MS (among 50% of patients with MS) and frequently represents the first well-documented manifestation of MS (in 20% of patients with MS).<sup>9–10,21,47</sup> Follow-up of the ONTT cohort to 15 years has continued to demonstrate that brain MRI is the most powerful predictor of subsequent MS risk in monosymptomatic patients.<sup>9–10,16</sup> The presence of one or more white matter lesions was associated with a 72% risk of MS after 15 years, whereas the risk was only 25% if the MRI results were normal (excluding optic nerve enhancement).<sup>9,16,52</sup> Overall, after 15 years of follow-up, the cumulative risk of developing MS after optic neuritis was 50%.<sup>53</sup> The risk with multiple lesions was not significantly higher than it was with a single lesion (58% versus 51%;  $P = 0.22$ , log rank test).<sup>16</sup> Monosymptomatic patients with one or more brain white matter lesions seen with MRI are, therefore, considered to be at high risk of the development of MS following acute demyelinating optic neuritis.

MS diagnostic criteria published in 2010 allow for diagnosis of MS in monosymptomatic patients with both enhancing and nonenhancing lesions on brain MRI.<sup>53</sup> Among patients with normal brain MRI findings

(no white matter lesions) in the ONTT, presence of optic disc swelling, mild visual acuity loss, and male gender were features associated with a reduced risk of MS.<sup>10,16</sup> Painless visual loss, total visual loss (no light perception), and ophthalmoscopic findings of severe disc swelling, hemorrhage of the optic disc or surrounding retina, or retinal exudates were features associated with a 0% risk of MS in these patients.<sup>16</sup> In patients with a normal baseline brain, certain features (severe optic disc swelling, hemorrhages, and exudates) suggest a low risk of developing MS.<sup>16</sup>

As in adults, optic neuritis is predictive of the subsequent risk of MS in children; one longitudinal study found that MS developed in 13% of children within 10 years of the first episode of optic neuritis, and in 19% within 20 years of the first episode.<sup>48</sup> A recent meta-analysis by Waldman and coworkers demonstrated that older age and the presence of brain lesions are the key factors in determining risk of MS. For every 1 year increase in age, the odds of developing MS after a unilateral episode of optic neuritis increase by 25% in children. In this analysis, 29% of children developed MS over the follow-up period of these studies (range of 0.1–31 years).<sup>54</sup> The risk of MS was greater in children with an abnormal MRI at presentation with an odds ratio of 28.<sup>54</sup>

## **PATHOLOGY**

Although the exact underlying cause is unknown, the pathophysiology of acute optic neuritis and MS is that of primary inflammatory demyelination.<sup>19–20</sup> Very little is written about the pathology of “isolated” optic neuritis, and no autopsy data have been reported. The inflammatory response in MS plaques is marked by perivascular cuffing, T cells, and plasma cells. Although MS itself previously was thought to be exclusively a disease of myelin with sparing of nerve axons, neuronal and axonal loss have been demonstrated to occur pathologically.<sup>19</sup>

## **TREATMENT**

One goal of acute therapy for optic neuritis is to improve visual outcome. These are the two major findings of the ONTT with regard to this treatment goal:

- Intravenous methylprednisolone treatment hastens recovery of visual function but does not affect long-term visual outcome; this benefit was greatest in the first 15 days.
- Patients treated with oral prednisone alone (without intravenous methylprednisolone) demonstrated an increased risk of recurrent optic neuritis (30% after 2 years versus 16% for the placebo group and 13% for those receiving intravenous corticosteroids) throughout the follow-up period of 10+ years (44% after 10 years versus 31% for the placebo group and 29% for those receiving intravenous corticosteroids).<sup>8,10,15</sup>

In the acute phase, it is important to recognize patients with possible NMO spectrum disorder based on AQP4-IgG status or history.<sup>49</sup> This is because studies suggest that such patients have a long-term outcome benefit associated with acute therapy with high-dose corticosteroids and therapeutic plasma exchange.<sup>51</sup>

Another goal of optic neuritis treatment is to delay development of clinically definite demyelinating disease. The ONTT demonstrated that monosymptomatic patients in the intravenous methylprednisolone group had a reduced rate of development of MS during the first 2 years of follow-up, but this benefit did not persist beyond 2 years and was seen only in patients with brain MRI scans that indicated a high risk for subsequent MS (originally described as MRI scans with two or more white matter lesions, 10-year follow-up data has confirmed one or more white matter lesions as an equivalent risk).<sup>9–10,16</sup>

Multiple MS therapies have been studied with regard to their ability to reduce cumulative probability of development of clinically definite MS in monosymptomatic patients with brain lesions on initial MRI. The Controlled High-Risk Avonex MS Prevention Study (CHAMPS) demonstrated that treatment with interferon  $\beta$ -1a (Avonex) following acute monosymptomatic demyelinating optic neuritis or other first demyelinating event (including brainstem syndrome or incomplete transverse myelopathy) significantly reduces the 3-year cumulative probability of MS and reduced rates of accumulation of clinically silent lesions on brain MRI.<sup>55</sup> Results were similar in the subgroup of patients in CHAMPS who experienced optic neuritis as their first demyelinating event (192 patients), supporting the initiation of interferon  $\beta$ -1a in optic neuritis patients at high risk for MS by MRI criteria.<sup>57</sup> All patients in CHAMPS (interferon  $\beta$ -1a and placebo groups) also received a 3-day course of intravenous methylprednisolone followed by oral prednisone as per the ONTT protocol. An extension study

(Controlled High-Risk Avonex Multiple Sclerosis Prevention Study in Ongoing Neurological Surveillance, known as CHAMPIONS) confirmed the potential for long-term benefit of interferon  $\beta$ -1a in patients with acute monosymptomatic demyelinating optic neuritis (or other first demyelinating event) and high-risk brain MRI findings.<sup>5</sup> Early interferon therapy following a first demyelinating event is likewise supported by results of a randomized trial of interferon $\beta$ -1a (Rebif) performed in Europe (Early Treatment of Multiple Sclerosis Study, ETOMS).<sup>58</sup>

Results from the Betaferon/Betaseron in Newly Emerging Multiple Sclerosis for Initial Treatment (BENEFIT) trial, involving 487 patients with a first clinical demyelinating event (80 patients with optic neuritis), suggest that 250  $\mu$ g of interferon  $\beta$ -1b (Betaseron) subcutaneously every other day delays the development of multiple sclerosis.<sup>59</sup> Compared with subjects receiving placebo, subjects in the interferon group were less likely to be diagnosed with MS (28% versus 45%) and had significantly fewer lesions on brain MRI than did patients in the placebo group.<sup>60</sup> This effect persisted in the 5-year extension study; early treatment reduced the risk of clinically definite MS by 37%.<sup>61</sup>

Glatiramer acetate (Copaxone) has also been demonstrated to be an effective treatment in the clinically isolated syndrome. The PreCISe study, a randomized, double-blind placebo-controlled trial of 481, demonstrated that Copaxone decreased the risk of conversion to clinically definite MS by 45% compared with placebo.<sup>62</sup> It is important to note that these trials were completed prior to a 2010 revision in MS diagnostic criteria, which allows for MS diagnosis based on a single MRI scan. It is likely that some of the subjects in these trials would have already met these new diagnostic criteria for MS at study entry.<sup>53</sup>

Teriflunomide, an oral therapy for multiple sclerosis, has demonstrated efficacy in reducing onset of clinically definite MS over 2 years in patients with clinically isolated syndrome, including optic neuritis, with two or more T2 lesions on MRI.<sup>63</sup>

## **Other Treatments**

In experimental models of MS, intravenous immunoglobulin G (IVIG) has been shown to promote remyelination of the central nervous system.<sup>64</sup> A small pilot study in 1992 suggested that IVIG treatment may have some benefit in patients with resolved optic neuritis who have significant visual deficits.<sup>65</sup> However, two recent randomized trials of IVIG versus placebo have failed to demonstrate any clinical benefit.<sup>64–66</sup>

## **Management Recommendations**

In patients with a typical clinical course and examination findings for acute monosymptomatic demyelinating optic neuritis (first demyelinating event), MRI of the brain (T2-enhanced and gadolinium-enhanced images) should be performed to determine whether they are at high risk for the development of MS. Characteristic demyelinating lesions in patients at risk of multiple sclerosis are 3 mm or larger in diameter, are ovoid, are located in periventricular areas of the white matter, and radiate toward the ventricular spaces.<sup>47,49–51</sup> Oligoclonal banding of proteins in the cerebrospinal fluid is a useful predictor of the risk of multiple sclerosis among patients with either normal brain MRI or abnormal findings that are not classic for demyelination (e.g., small, punctate lesions that are not periventricular or ovoid).<sup>56</sup> The presence of two or more white matter lesions on MRI (3 mm diameter or larger, at least one lesion periventricular or ovoid) should prompt consideration of one of these treatments<sup>1–16,47,55–62,67</sup>:

- Interferon  $\beta$ -1a (Avonex 30  $\mu$ g intramuscularly once a week).
- Interferon  $\beta$ -1a (Rebif 22  $\mu$ g subcutaneously once a week).
- Betaseron (250  $\mu$ g subcutaneously every other day).
- Glatiramer acetate (Copaxone 20 mg subcutaneously daily).
- Teriflunomide.

In monosymptomatic patients without white matter lesions, with enhancing and nonenhancing white matter lesions that meet criteria for diagnosis of MS and in patients for whom a diagnosis of MS has been previously established, intravenous methylprednisolone treatment (1 g per day, single or divided doses, for 3 days) followed by oral prednisone (1 mg/kg per day for 11 days, then 4-day taper) may be considered on an individual basis to hasten visual recovery, but this has not been demonstrated to improve long-term visual outcome. Effects of corticosteroid treatment and other therapies on the recovery of visual function and on the risk of multiple sclerosis in children have not been established by randomized trials, but intravenous methylprednisolone treatment is generally recommended if visual loss is unilateral and severe or is bilateral.<sup>58</sup>

In monosymptomatic patients with AQP4-IgG in their serum who meet criteria for NMO spectrum disorder or who are judged to be at high risk for NMO spectrum disorder, intravenous methylprednisolone (1 g per day for 5 days) followed by an oral corticosteroid taper should be considered. A second course of high-dose corticosteroids or a course of therapeutic plasma exchange can be considered in patients with progression or poor recovery.<sup>51</sup>

Based on findings from the ONTT, oral prednisone alone (without prior treatment with intravenous methylprednisolone) may increase the risk of recurrent optic neuritis and should be avoided.

A short course of noncorticosteroidal anti-inflammatory agents may be helpful in the occasional case of disabling pain associated with optic neuritis.<sup>31</sup>

## COURSE AND OUTCOME

At least some visual improvement is expected in all patients who have acute demyelinating optic neuritis. Visual improvement usually begins rapidly in patients treated with intravenous methylprednisolone. Even with no treatment, however, most patients start to recover vision within 2–3 weeks of symptom onset. Once recovery begins, most patients achieve near maximal improvement within 1–2 months, although recovery up to 1 year is possible. Severity of the initial visual loss appears to be the only predictor of visual outcome.<sup>2,15</sup>

Despite favorable recovery of vision, frequently to 20/20 or better (as was seen in 74% of patients in 10-year ONTT follow-up),<sup>15</sup> many patients with acute demyelinating optic neuritis continue to experience subtle visual abnormalities that affect their daily function and quality of life. They may report that their vision seems blurred, washed out, or “not right.”<sup>12–13</sup> Persistent abnormalities of visual acuity (15%–30%), contrast sensitivity (63%–100%), color vision (33%–100%), the visual field (62%–100%), stereopsis (89%), light brightness sense (89%–100%), afferent pupillary reaction (55%–92%), optic disc appearance (60%–80%), and the visual-evoked potential (63%–100%) have been demonstrated in such patients. Recurrent episodes of optic neuritis in the initially affected or fellow eye may

occur also. Approximately 35% of placebo-group ONTT participants had a second episode in either eye within the 10-year follow-up period, and risk of recurrence is twofold greater in patients with an MS diagnosis at any time during 10-year follow-up than in patients who do not develop MS (48% versus 24%,  $P < 0.001$ ).<sup>9,15</sup>

During and even beyond the recovery of vision following acute demyelinating optic neuritis, patients frequently experience transient worsening of symptoms with exposure to heat (Uhthoff's symptom).<sup>59</sup> Positive visual phenomena and photopsias are also common and were reported by 30% of ONTT participants.<sup>1,3</sup>

Ischemic Optic Neuropathy

Anthony C. Arnold, Michelle Y. Wang

9.8

**Definition:** Acute, painless optic neuropathy occurring predominantly in patients over 50 years of age.

Key Features

- Optic disc edema.
- Dimming of vision, dyschromatopsia, afferent pupillary defect, and altitudinal or other optic disc-related visual field loss (in anterior ischemic optic neuropathy).
- No evidence of demyelination.
- Normal optic disc appearance (in posterior ischemic optic neuropathy).
- Pallor (in arteritic anterior ischemic optic neuropathy).

Associated Features

- Peripapillary flame hemorrhages.
- Peripapillary arteriolar narrowing.

ISCHEMIC OPTIC NEUROPATHY

INTRODUCTION

Optic nerve ischemia most frequently occurs at the optic nerve head, where, in susceptible individuals, structural crowding of nerve fibers and the relative reduction of the vascular supply combine to impair perfusion to a critical degree and produce optic disc edema. The most common such syndrome is termed anterior ischemic optic neuropathy (AION).<sup>1</sup> Generally, AION is categorized as either arteritic (associated with temporal arteritis) or nonarteritic (Table 9.8.1). Optic nerve ischemia affects the intraorbital portion of the nerve less frequently, with no visible disc edema, and this has been termed posterior ischemic optic neuropathy.

TABLE 9.8.1 Comparison of Major Features of Arteritic and Nonarteritic Anterior Ischemic Optic Neuropathy (AION)

Feature	Arteritic AION	Nonarteritic AION
Age (mean years)	70	60
Sex ratio	Female > male	Male = female
Associated symptoms	Headache, scalp tenderness, jaw claudication	Mild pain occasionally noted
Visual acuity	Up to 76% <20/200 (6/60)	Up to 61% >20/200 (6/60)
Disc	Pale > hyperemic edema Cup normal	Hyperemic > pale edema Cup small
Mean erythrocyte sedimentation rate (mm/hour)	70	20–40
Fluorescein angiogram	Disc and choroid filling delay	Disc filling delay
Natural history	Improvement rare Fellow eye in up to 95%	Improvement in up to 43% Fellow eye in <30%
Treatment	Corticosteroids	None proved

ANTERIOR ISCHEMIC OPTIC NEUROPATHY

Epidemiology and Pathogenesis

Nonarteritic anterior ischemic optic neuropathy (NAION) is the most common acute optic neuropathy in patients over 50 years of age, with an estimated annual incidence in the United States of 2.3–10.2 per 100 000 population,<sup>2,3</sup> some 6000–8000 new cases each year. Subsequent studies have shown that AION is not so unusual before the age of 50.<sup>4</sup> No gender predisposition exists, but the disease occurs with significantly higher frequency in white than in black or Hispanic populations.<sup>2,5</sup> The incidence of arteritic anterior ischemic optic neuropathy (AAION) is lower.<sup>2</sup>

Arteritic Anterior Ischemic Optic Neuropathy

Ample evidence exists that AAION results from short posterior ciliary artery (SPCA) vasculitis and the resultant optic nerve head infarction. Human autopsy studies of acute AAION demonstrate optic disc edema with ischemic necrosis of the prelaminar, laminar, and retrolaminar portions of the nerve and infiltration of the SPCAs by chronic inflammatory cells. Segments of these vessels in some cases were occluded by inflammatory thickening and thrombus.<sup>6</sup>

Fluorescein angiographic data support the histopathological evidence of involvement of the SPCAs in AAION.<sup>7</sup> Delayed filling of the optic disc and choroid is a consistent feature; extremely poor or absent filling of the choroid has been depicted as a characteristic of AAION and has been suggested as one useful factor by which to differentiate AAION from NAION. Delayed completion of choroidal fluorescein filling that averages 30–69 seconds has been reported in AAION, compared with a mean of 5–13 seconds in NAION.<sup>8</sup>

Nonarteritic Anterior Ischemic Optic Neuropathy (NAION)

The rapid onset, stable course with generally poor recovery, association with vasculopathic risk factors, and similarity to AAION implies a vascular cause for NAION as well, but the direct evidence remains limited.<sup>9</sup> Several histopathological reports document laminar and retrolaminar infarction, but cases of uncomplicated NAION are rare, and none has confirmed vasculopathy within the SPCAs or their distal branches. The most commonly proposed pathogenic theory states that insufficiency of the optic disc circulation is exacerbated by structural crowding of nerve fibers and supporting structures at the nerve head and eventually reaches a point at which inadequate oxygenation produces ischemia and swelling of the disc. These features may be mild and subclinical (no visual loss), reversible to some degree, or irreversible (infarction). In some cases, a cycle of ischemia, axonal swelling, microvascular compression, and further ischemia may lead to progressive nerve damage. Periodic nocturnal systemic hypotension and that the optic disc is in a watershed zone between distributions of lateral and medial SPCAs may be contributing factors.<sup>10</sup>

Fluorescein angiographic studies in NAION also suggest impaired optic disc perfusion. Detailed quantitative analysis of prelaminar optic disc and peripapillary choroidal filling in NAION confirms delayed disc filling when compared with age-matched controls.<sup>11</sup> Delay in a segment of disc (Fig. 9.8.1) by at least 5 seconds was present in 75.6% of such cases.<sup>12</sup> In contrast, peripapillary choroidal filling was not delayed consistently compared to normal subjects. Significantly delayed optic disc filling is characteristic of ischemia, which is not seen in disc edema from nonischemic causes such as papilledema.<sup>13</sup> Optical coherence tomography angiography, a new diagnostic imaging device, may add additional insights into peripapillary microvasculature and extent of ischemia in NAION.<sup>14</sup>

**Fig. 9.8.1** Fluorescein Angiogram, Early Arteriovenous Phase, in Nonarteritic Anterior Ischemic Optic Neuropathy. The temporal portion of the optic disc fills normally (*small arrows*), but the remaining sectors demonstrate markedly delayed filling (*large arrows*) approximately 10 seconds later.

**Fig. 9.8.3** Fundus View, Nonarteritic Anterior Ischemic Optic Neuropathy. The hyperemic disc edema is more prominent superiorly. Focal surface telangiectasia of disc vessels is seen superotemporally (*arrows*).

**Fig. 9.8.2** Fundus View, Anterior Ischemic Optic Neuropathy. The optic disc demonstrates pale, diffuse edema.

## Ocular Manifestations

AION presents with rapid onset of painless, unilateral visual loss manifested by decreased visual acuity, visual field, or both. The level of visual acuity impairment varies widely, from minimal loss to no light perception, and the visual field loss may conform to any pattern of deficit related to the optic disc. An altitudinal field defect is most common, but generalized depression, broad arcuate scotomas, and cecocentral defects also are seen. A relative afferent pupillary defect is present with monocular optic neuropathy. The optic disc is edematous at onset, and edema occasionally precedes visual loss by weeks to months.<sup>15</sup> Although pallid edema has been described as the hallmark of AAION (Fig. 9.8.2), it is common to see hyperemic swelling (Fig. 9.8.3), particularly in the nonarteritic form. The disc most often is swollen diffusely, but a segment of more prominent involvement may be present (see Fig. 9.8.3), and either focal or diffuse surface telangiectasia is not unusual and may be quite pronounced. Commonly, flame hemorrhages are located adjacent to the disc, and the peripapillary retinal arterioles frequently are narrowed.

### Arteritic Anterior Ischemic Optic Neuropathy

In 5%–10% of cases, AION may occur as a manifestation of the vasculitis associated with temporal arteritis. Patients with the arteritic form note other symptoms of the disease—headache, jaw claudication, and temporal

artery or scalp tenderness are those aligned most frequently with a final diagnosis of temporal arteritis. Malaise, anorexia, weight loss, fever, proximal joint arthralgia, and myalgia also are noted commonly, but the disease rarely manifests with visual loss in the absence of overt systemic symptoms, so-called occult temporal arteritis.

Typically, AAION develops in patients over 50 years—with a mean age of 70 years—with severe visual loss (visual acuity <20/200 [6/60] in the majority). However, this mean is misleading, reflecting the ascertainment bias of fewer individuals who survive to the oldest ages. In fact, AAION probably increases in frequency with every decade. A recent study showed that AAION is the most common cause of vision loss in patients with giant cell arteritis.<sup>16</sup> Among those with permanent vision loss, the average age was 82 years as compared to 76 years in the remaining group. AAION may be preceded by transient visual loss similar to that of carotid artery disease; this finding is extremely unusual in the nonarteritic form and, when present, is highly suggestive of arteritis.<sup>17</sup> Pallor of the optic disc, which may be severe, chalky white, is associated with AAION. Choroidal ischemia may be associated with the optic neuropathy and produces peripapillary pallor and edema deep to the retina. The disc of the fellow eye is of normal diameter in AAION.<sup>18</sup>

### Nonarteritic Anterior Ischemic Optic Neuropathy

In 90%–95% of cases, AION is unrelated to temporal arteritis. The nonarteritic form of the disease occurs in a somewhat younger age group (mean age of 60 years) and usually is associated with less severe visual loss. Frequently, visual impairment is reported on awakening, possibly related to nocturnal systemic hypotension. The initial course of visual loss usually is static (with little or no fluctuation of visual level after the initial loss) but may be progressive (with either episodic or visual loss that declines steadily over weeks). The progressive form has been reported in up to 37% of NAION cases.<sup>19</sup> Usually, no associated systemic symptoms occur, although periorbital pain is occasionally described. Fellow eye involvement is estimated to occur in 12%–19% by 5 years after onset.<sup>20</sup> Recurrent episodes of visual loss that result from NAION in the same eye are very unusual.

The optic disc edema in NAION may be diffuse or segmental, hyperemic or pale, but pallor occurs less frequently than it does in AAION. A focal region of more severe swelling is often seen and typically displays an altitudinal distribution, but it does not correlate consistently with the sector of visual field loss.<sup>11</sup> Diffuse or focal telangiectasia (see Fig. 9.8.3) of the edematous disc may be present, occasionally prominent enough to resemble a vascular mass or neovascularization. This finding may represent microvascular shunting from ischemic to nonischemic regions of the optic nerve head, so-called luxury perfusion. The optic disc in the contralateral eye typically is small in diameter and demonstrates a small or absent physiological cup.<sup>18</sup> The disc appearance in such fellow eyes (Fig. 9.8.4) has been described as the disc-at-risk, with postulated structural crowding of the axons at the level of the cribriform plate, associated mild disc elevation, and disc margin blurring without overt edema.

**Fig. 9.8.4 Fellow Eye in Nonarteritic Anterior Ischemic Optic Neuropathy.** The optic disc is small in diameter, with absent physiological cup and slight blurring of the nasal margin.

## Diagnosis and Ancillary Testing

The most important early step in the management of AION is the differentiation of the arteritic from the nonarteritic form of the disease. Measurement of the inflammatory markers remains the standard of care. Active temporal arteritis usually is associated with an elevation of erythrocyte sedimentation rate (ESR) to 70–120 mm/hour, and this finding suggests the arteritic form; in most cases, it should prompt immediate corticosteroid therapy and confirmatory temporal artery biopsy (see later). The test carries a significant rate of both false positives and false negatives, however, with normal measurements found in an estimated 16% of biopsy-proved cases.<sup>21</sup> Conversely, abnormally high readings occur normally with increasing age and with other diseases, most commonly occult malignancy, other inflammatory disease, and diabetes. Measurement of serum C-reactive protein (CRP), another acute phase plasma protein, may aid in diagnosis. Hayreh et al.<sup>22</sup> reported 97% specificity for temporal arteritis in cases of AION in which both ESR greater than 47 mm/hour and CRP greater than 2.45 mg/dL were found. However, elevated platelet count may have the strongest association with positive temporal artery biopsy when compared to CRP and ESR.<sup>23</sup> When two or more inflammatory markers were elevated, the association was highest. Several proinflammatory cytokines have been identified in AAION. Of those, interleukin-6 (IL-6) gained much more interest as it also plays an important role in acute-phase response induction. Plasma IL-6 has also been suggested as a biological marker of AAION disease activity.<sup>24</sup>

Confirmation of the diagnosis of temporal arteritis by superficial temporal artery biopsy is often recommended in cases of AION in which a clinical suspicion of arteritis exists based on age, associated systemic symptoms, severity of visual loss, and elevated ESR and CRP levels. Positive biopsy findings, such as intimal thickening, internal limiting lamina fragmentation, and chronic inflammatory infiltrate with giant cells, provide support for long-term systemic corticosteroid therapy (Fig. 9.8.5). A negative biopsy result, however, does not rule out arteritis. Both discontinuous arterial involvement (“skip lesions”) and solely contralateral temporal artery inflammation may result in false-negative results. A 3%–5% false-negative error rate has been reported.<sup>25</sup>

As previously mentioned, fluorescein angiography (FA) can be a very helpful diagnostic tool by providing visualization of perfusion of choroid, retina, and both deep (prelaminar) and inner surface of the optic disc. The FA filling characteristics can help differentiate optic disc edema secondary to ischemia from other causes. Markedly delayed in choroidal filling is characteristic of AAION. Optic coherence tomography (OCT) is another useful tool (see Chapter 9.2). Sectoral disc edema, retinal nerve fiber layer (RNFL) thickness, and then resolution to normal or atrophy can be well documented.<sup>26</sup> The extent and pattern of RNFL loss can be correlated to visual field loss.<sup>27</sup> This can provide a useful metric against which purported treatment for AION can be assessed.

**Fig. 9.8.5 Typical Temporal Arteritis.** (A) Histological section shows a vasculitis involving all coats of the temporal artery. (B) Increased magnification shows the typical giant cell granulomatous inflammation. (Courtesy Dr. M. M. Rodrigues.)

## Differential Diagnosis

The differential diagnosis of AION includes idiopathic optic neuritis, particularly in patients under 50 years of age; other forms of optic nerve inflammation, such as those related to syphilis or sarcoidosis; infiltrative optic neuropathies; anterior orbital lesions that produce optic nerve compression; and diabetic papillopathy. Diabetic papillopathy (discussed later) may represent a forme fruste AION with reversible signs and symptoms after several months. Optic neuritis may resemble AION with regard to rate of onset, pattern of visual field loss, and optic disc appearance. In most cases, however, the patient's age, lack of pain with eye movement, and pallor or segmental configuration of the disc edema enables differentiation. Early disc filling delay on FA may confirm ischemia. Syphilitic or sarcoid-associated optic neuritis often is associated with other intraocular inflammatory signs, which should prompt further testing. Orbital lesions typically produce gradually progressive visual loss. Associated signs of orbital disease, such as mild exophthalmos, lid abnormalities, or eye movement limitation, may suggest the use of neuroimaging to detect anterior orbital inflammation or tumor.

## Systemic Associations

AAION is known to be a manifestation of temporal arteritis. NAION has been reported in association with a number of diseases that could predispose to reduced perfusion pressure or increased resistance to flow within the optic nerve head. Systemic hypertension has been documented in up to 47% of patients who have NAION<sup>28</sup> and diabetes in up to 40%.<sup>29</sup> Obstructive sleep apnea has been reported in up to 89% of patients with NAION but there are many confounders.<sup>30</sup> Hypercholesterolemia, smoking, anemia, chronic renal failure, and migraine have all been reported as potential risk factors.

Whether cataract surgery has an association with NAION has been controversial. Lam et al. found that in patients with unilateral NAION, the risk of NAION in the fellow eye was increased by 3.6-fold when the fellow

eye underwent cataract surgery.<sup>31</sup> Another study did not find significant temporal relationship.<sup>32</sup>

Carotid occlusive disease itself is not causative with NAION. However, indirect evidence shows increased central nervous system, small vessel, ischemic disease in patients who have NAION, based on magnetic resonance imaging (MRI) data.<sup>33</sup> Studies indicate that cerebrovascular or cardiovascular events are both more common than in the normal population, particularly in patients who have hypertension or diabetes.<sup>34</sup> Subsequent mortality, however, is not affected.

Also, NAION has been reported in association with multiple forms of vasculitis, acute systemic hypotension, and optic disc drusen. Other risk factors have been proposed, such as hyperopia and the presence of human lymphocyte antigen A.<sup>35</sup> Associations of hyperhomocysteinemia with AION, particularly in patients under 50, are inconclusive.<sup>36</sup> Prothrombotic risk factors, such as protein C and S and antithrombin III deficiencies, factor V Leiden mutation, and cardiolipin antibodies, have rarely been reported in association with AION.<sup>37</sup> Screening in patients under age 50 may be considered as treatment and may reduce involvement of fellow eye.

Certain medications have been associated with NAION. The association between amiodarone and NAION has been controversial, as patients taking amiodarone typically carry other vascular risk factors. The association is more likely when the process is insidious, bilateral, and chronic.<sup>38</sup> Thirty-nine cases of NAION have been reported in association with ingestion of phosphodiesterase 5 inhibitor, including sildenafil (Viagra), tadalafil (Cialis), and vardenafil (Levitra).<sup>39</sup> Some authors speculated that these medications induce systemic hypotension exacerbated by nocturnal hypotension in predisposed optic discs. Association with interferon-alpha has also been proposed, possibly secondary to medication-induced systemic hypotension or immune complex deposition.<sup>40</sup>

## Treatment

### Arteritic Anterior Ischemic Optic Neuropathy

Early treatment of AAION is essential and must be instituted immediately in any suspected case of temporal arteritis. High-dose systemic corticosteroids are standard; the use of intravenous methylprednisolone at 1 g/day for the first 3 days has been recommended for some AAION patients in the acute phase of severe involvement. Oral prednisone in the range of 60–100 mg/day may be used initially and for follow-up to intravenous pulse therapy; alternate day regimens do not suppress the disease effectively. Treatment usually reduces systemic symptoms within several days. A positive response is so typical that if it does not occur, an alternate disease process should be considered. Treatment is usually continued at high dose for several months before beginning taper. AAION remains a serious ophthalmic condition requiring timely diagnosis and treatment. Studies have undertaken to understand the immunopathology and to guide more targeted therapy.<sup>41</sup> For cases of AAION that do not respond to or are unable to tolerate corticosteroids, investigators have tried corticosteroid-sparing agents such as anti-TNF- $\alpha$  antibodies with various results.<sup>42</sup> More recently, a randomized double-blind placebo-controlled trial (GiACTA) was conducted to investigate the efficacy and safety of tocilizumab as a new adjuvant therapy for AAION.<sup>43</sup> Tocilizumab is a humanized monoclonal anti-IL6 receptor antibody. In the study, tocilizumab was found efficacious for induction and maintenance of remission in patients with AAION on prednisone taper. Relapse-free survival by week 52 was achieved in 85% of patients in the tocilizumab group and only 20% in the placebo group. The time difference to stop corticosteroids was 12 weeks in favor of the tocilizumab group, leading to significantly less cumulative dose of corticosteroids. The long-term efficacy of tocilizumab has not been determined.

### Nonarteritic Anterior Ischemic Optic Neuropathy

There is no proven effective therapy for NAION, and the use of corticosteroids in NAION is highly controversial. Hayreh and Zimmerman studied the effect of oral prednisone in the acute phase of NAION and found significant improvement in visual acuity and visual fields up to 6 months after onset.<sup>44</sup> The rationale for vision improvement is that corticosteroids may alter capillary permeability and reduce optic disc edema, thereby relieving compartment syndrome and improving circulation in the optic nerve head. However, the result of this study is controversial as it was not randomized or blinded, and the noncorticosteroid-treated cohort may have been influenced by a ceiling effect (their visual acuities were often very good to start with). Optic nerve sheath decompression (ONSD) surgery has been attempted, based on the theory that reduction of perineural subarachnoid cerebrospinal fluid pressure might improve local vascular flow

**Fig. 9.8.6 Optic Disc, Nonarteritic Anterior Ischemic Optic Neuropathy.** The disc, 2 months after onset of inferior visual field loss, is segmentally atrophic superiorly (arrows), with sparing and resolving edema inferiorly.

or axoplasmic transport in the optic nerve head and thus reduce tissue injury in reversibly damaged axons.

The Ischemic Optic Neuropathy Decompression Trial compared ONSD surgery in 119 patients with no treatment in 125 controls.<sup>5</sup> The study revealed no significant benefit for treatment and a possible harmful effect; it was recommended that ONSD not be performed for NAION. Hyperbaric oxygen, by marked elevation of the dissolved oxygen content in the blood, provides increased tissue oxygenation that might reduce damage in reversibly injured axons. A controlled clinical pilot study of hyperbaric oxygen in 22 patients who had acute NAION, however, has shown no beneficial effect.<sup>45</sup> Johnson et al.<sup>46</sup> reported a beneficial effect for oral levodopa on the visual outcome for NAION, but the study was controversial,<sup>35</sup> and the effect is considered unproved. Neuroprotective agents have shown a beneficial effect in animal models of optic nerve damage but are not proven to be effective in NAION. The effect of aspirin in reducing risk of fellow eye involvement is also unproved.<sup>47</sup>

## Course and Outcome

### Arteritic Anterior Ischemic Optic Neuropathy

The major goal of therapy in AAION is to prevent visual loss in the fellow eye. Untreated, such involvement occurs in 54%–95% of cases,<sup>48,49</sup> typically within 4 months. With corticosteroid therapy, the rate of such breakthrough is reduced to an estimated 13%. Prognosis for visual recovery in the affected eye that has treatment generally is poor, and worsening of vision in spite of therapy has been reported in 9%–17% of cases.<sup>48</sup> A study reports a 3-day course of induction intravenous corticosteroids (1000 mg/day) may reduce long-term cumulative doses of corticosteroid.<sup>50</sup>

### Nonarteritic Anterior Ischemic Optic Neuropathy

The course of untreated NAION varies considerably. Reports indicate that 24% to 43% of cases demonstrate spontaneous improvement of visual acuity by three Snellen lines or more.<sup>5</sup> Even in the progressive form, improvement has been reported to occur in roughly 30% of cases. Whether NAION is static or progressive, visual acuity and field stabilize after several months. Within 6 weeks, the optic disc becomes visibly atrophic, either in a sectoral (Fig. 9.8.6) or diffuse pattern. Further progression or recurrent episodes are extremely rare after 2 months and, if present, should prompt evaluation for another cause of optic neuropathy.

## POSTERIOR ISCHEMIC OPTIC NEUROPATHY

Ischemia of the optic nerve that does not involve the optic nerve head is termed posterior ischemic optic neuropathy (PION). It presents with acute visual loss associated with signs of optic neuropathy (afferent pupillary defect and visual field loss) in one or both eyes, with initially normal appearance of the optic disc, which subsequently becomes atrophic.

**Fig. 9.8.7 Optic Disc in Diabetic Papillopathy.** (A) Nonspecific hyperemic disc edema. (B) Surface vessels show marked telangiectasia, in which dilated vessels generally follow a radial distribution. (C) Contrast with diabetic optic disc neovascularization; note the irregular, random branching pattern of surface vessels.

The diagnosis of PION is most often made in one of two settings:

- *Vasculitis*, most importantly, giant cell arteritis (GCA); evaluation for GCA should be the primary consideration with this presentation in the elderly, or
- The combination of *systemic hypotension and anemia*, usually related to blood loss either from surgery (coronary artery bypass and lumbar spine procedures most commonly),<sup>51</sup> gastrointestinal bleed, or trauma. This was originally referred to as shock-induced optic neuropathy.

The differential diagnosis includes compressive, inflammatory, and infiltrative optic neuropathies, although the onset in PION is typically more abrupt. In most cases, neuroimaging is indicated to rule out these possibilities.

Sadda et al. reported a multicenter, retrospective review of 72 patients with PION, adding a third classification paralleling the nonarteritic form of AION.<sup>52</sup> The nonarteritic PION group accounted for 38 of the 72 patients, exhibited similar risk factors, and followed a clinical course precisely like that of NAION. Perioperative and arteritic PION was characterized by severe visual loss with little or no recovery. It is important to recognize this nonarteritic form in patients with acute optic neuropathy but no optic disc edema, a scenario that may be mistaken for retrobulbar optic neuritis. Such patients, particularly those with ischemic white-matter lesions on MRI, might be incorrectly begun on immunomodulatory therapy to reduce the risk of multiple sclerosis. This PION mechanism may also present

with disc swelling and hemorrhages and is a form of NAION, although it differs in usually occurring postsurgery or other causes of severe blood loss.

## DIABETIC PAPILLOPATHY

### PATHOGENESIS AND FEATURES

The pathogenesis of diabetic papillopathy is unclear. The most commonly proposed theory suggests diabetic papillopathy to be a mild form of NAION, with reversible ischemia of both the prelaminar and inner surface layers of the optic nerve head.<sup>53</sup> Edema of the optic nerve head in the absence of significant visual dysfunction occurs in several presumed vascular disorders as follows:

- Asymptomatic optic disc edema, which evolves to typical NAION weeks to months after initial symptoms.
- Asymptomatic disc edema of the fellow eye in patients who have NAION, which may either progress to NAION or resolve spontaneously.
- Disc edema in association with systemic hypertension, which resolves without sequelae as blood pressure is normalized.

Diabetic papillopathy fits this category as well. The prominent surface telangiectasias may represent vascular shunting from prelaminar to

ischemic vascular beds. The frequent occurrence of a crowded optic disc in the fellow eye (see later),<sup>54</sup> as in NAION, also supports an ischemic mechanism.

The currently accepted criteria for the diagnosis of diabetic papillopathy include:

- Presence of diabetes (approximately 70% type 1, 30% type 2).
- Optic disc edema (unilateral in roughly 60%).
- Only mild optic nerve dysfunction.

The absence of ocular inflammation or elevated intracranial pressure also is essential to the diagnosis.

Although younger patients predominate (approximately 75% of those reported are under the age of 50 years), those affected may be of any age and typically experience mild visual complaints, such as mild blurring or distortion. Visual acuity is usually only mildly impaired; over 75% of reported cases measured 20/40 (6/12) or better. Macular edema contributes to visual acuity loss in many cases. OCT is invaluable in detecting this. Pain is absent, as are other ocular or neurological symptoms.

The involved optic discs may demonstrate either nonspecific hyperemic edema or marked telangiectasia of the inner surface microvasculature (Fig. 9.8.7A and B); pale swelling typically has been a criterion for exclusion and suggests AION. The surface telangiectasia is so prominent in many cases that it may be mistaken for neovascularization (see Fig. 9.8.7C). The fellow eye frequently demonstrates crowding, with a small cup-to-disc ratio similar to the configuration seen in patients who have NAION.

Diabetic retinopathy usually is present (in more than 80% of reported cases) at the time of onset of papillopathy, but it varies in severity. Often diabetic papillopathy is precipitated by a rapid drop from a very high HbA1C.<sup>55</sup> It is associated with cystoid macular edema in about 25% of cases and neovascularization in approximately 9%.

## COURSE AND OUTCOME

Although systemic corticosteroids have been used in isolated cases, no proven therapy exists for this disorder. Untreated, the optic disc edema

gradually resolves over a period of 2–10 months to leave minimal optic atrophy in about 20% of cases and subtle, if any, visual field loss. Visual acuity at the time of resolution of edema is 20/40 (6/12) or better in about 80% of cases; the remainder of patients suffer visual impairment because of maculopathy. The long-term visual prognosis for patients who have diabetic papillopathy, however, is limited by the associated diabetic retinopathy.

# Hereditary, Nutritional, and Toxic Optic Atrophies

## 9.9

Rustum Karanjia, Vivek R. Patel, Alfredo A. Sadun

**Definition:** Leber's hereditary optic neuropathy arises from an inherited point mutation in mitochondrial DNA and manifests in young adulthood as a distinctive hereditary optic neuropathy.

Nutritional deficiency states, particularly those that involve lack of certain vitamins (e.g., B12 or folic acid) and amino acids used in mitochondrial metabolism (e.g., homocysteine or methionine), can result in a stereotypical optic neuropathy.

Toxins and antibodies may interfere with mitochondrial metabolism on an acquired basis (e.g., ethambutol), producing an optic neuropathy.

### Key Features

- Symmetrical visual impairments.
- Loss of central visual acuity.
- Dyschromatopsia.
- Centrocecal visual field defects.
- Temporal optic disc pallor.
- Nerve fiber layer loss in the papillomacular bundle.

### Associated Features

- Loss of hearing.
- Peripheral neuropathy.

## INTRODUCTION

Hereditary, nutritional, and toxic optic neuropathies selectively affect the papillomacular bundle (PMB) of the human optic nerve, resulting in a characteristic bilateral central or centrocecal scotoma with preservation of some degree of peripheral vision. This peculiar susceptibility of the PMB appears to be underwritten by genetic or acquired mitochondrial dysfunction.<sup>1</sup> The hereditary causes include the prototypical disease of Leber's hereditary optic neuropathy (LHON), dominant optic neuropathy (Kjer's disease), Friedreich's ataxia, and Wolfram syndrome (characterized by diabetes insipidus, diabetes mellitus, optic atrophy, and deafness—DIDMOAD). The acquired diseases include toxic effects of drugs, including chloramphenicol, ethambutol, and linezolid and dietary deficiencies of B vitamins and folate, which are typified by tobacco-alcohol amblyopia (TAA) and the Cuban epidemic of optic neuropathy (CEON).<sup>1</sup>

The understanding of these optic neuropathies has evolved, but the characterization and study of the prototypical disease of LHON was first described in 1871 as a disease that produced a subacute onset of dyschromatopsia and sequential, bilateral visual loss, primarily in young men.<sup>2</sup> In 1988, Wallace and coworkers<sup>3</sup> identified the genetic defect as a point mutation in the mitochondrial DNA (and hence involving maternal inheritance). Three commonly reported mitochondrial DNA point mutations account for over 90% of the case of LHON. All the mutations affect complex I of the respiratory chain. The resulting impairment of energy production and chronic increase in reactive oxygen species are the underlying pathogenic mutations leading to optic nerve degeneration.<sup>4,5</sup> The fundus appearance is unusual, revealing characteristic optic disc changes and loss of the papillomacular nerve fiber layer.<sup>2</sup>

On the acquired side, TAA refers to a well-described combined toxic and nutritional deficiency. Traquair<sup>6</sup> emphasized that heavy drinking and smoking could lead to a slow, progressive, bilateral visual field loss. TAA

is now thought to result from the cyanide from tobacco and low levels of B12 brought about by poor nutrition and poor absorption associated with alcohol consumption.<sup>7</sup> Deficiencies of B12, other B vitamins, and in particular folic acid are known to result in a similar clinical picture.<sup>8</sup> Furthermore, a number of toxins, such as chloramphenicol, ethambutol, and linezolid, injure the optic nerve and produce a virtually indistinguishable clinical picture.<sup>9–11</sup> Indeed, it is one of the fundamental curiosities of these disorders that they, along with LHON, all have such similar and characteristic clinical manifestations.<sup>12,13</sup> In considering toxic agents that are best known to cause optic neuropathy, it is remarkable that most are known to interfere with mitochondrial oxidative phosphorylation.<sup>13</sup>

## EPIDEMIOLOGY AND PATHOGENESIS

Each of these optic atrophies has its own distinct incidence, prevalence, and pathogenesis. The prevalence of the toxic and nutritional optic neuropathies is dependent on extrinsic factors and thus varies between populations. Again, our knowledge of the hereditary optic neuropathies is best understood through the study of LHON, which is one of the most frequently occurring mitochondrial diseases.<sup>14</sup> The prevalence of LHON is about 1 in 30 000.<sup>15</sup> Penetrance is variable, affecting men more often than women, although the ratio depends on the pedigree.<sup>14,16</sup> The severity of the visual loss is greater for 3460/ND1 and 11778/ND4 and less for the 14484/ND6 mutation.<sup>2</sup>

The PMB is the main locus of the problem, eventually atrophying in most cases.<sup>2,17,18</sup> Injury to the PMB probably begins with impairments in mitochondrial oxidative phosphorylation. The resultant decrease in adenosine 5'-triphosphate (ATP) may compromise axonal transport, which, paradoxically, is highly energy dependent.<sup>19</sup> There is also a concurrent rise in reactive oxygen species (ROS) that can trigger apoptosis.<sup>14</sup>

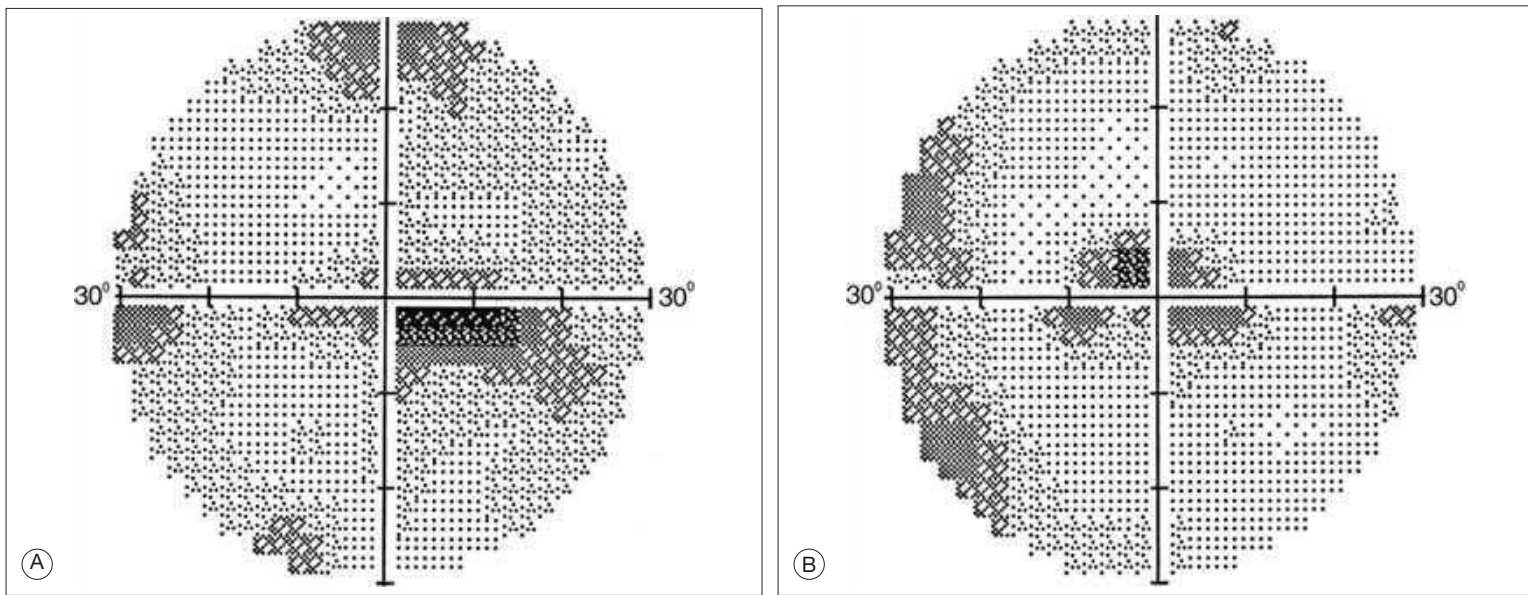

Toxic and nutritional deficiency optic neuropathies are fairly uncommon causes of optic neuropathy in the United States and Western Europe. CEON, however, serves to remind us that these types of optic neuropathies may be far more common in the developing world.<sup>20</sup> This family of diseases makes a resurgence in times of famine, new application of pharmaceuticals, or changes in the workplace that lead to nutritional deficiencies or toxic exposures.

Deficiencies in B-complex vitamins, including B1 (thiamine), B2 (riboflavin), and B12 (cobalamin), as well as folate, are the most commonly implicated nutritional deficiencies leading to nutritional optic neuropathy. Proteins containing sulfur amino acids are also crucial for efficient mitochondrial oxidative phosphorylation. Toxins established most clearly as producers of an optic neuropathy include arsacetin, carbon monoxide, clioquinol, cyanide, ethambutol, hexachlorophene, isoniazid, lead, linezolid, methanol, plasmocid, and triethyl tin. These agents interfere with mitochondrial oxidative phosphorylation.<sup>21–24</sup>

Ethambutol optic neuropathy is a particularly well-characterized and common mitochondrial cause of blindness.<sup>9,10,13</sup> There are an estimated 100 000 new cases of avoidable and permanent visual loss due to ethambutol annually.<sup>9</sup> While there is no universally safe dose of ethambutol (toxicity has been noted at doses <15 mg/kg/day), dosing should take into account the patient's weight, age, and renal function.<sup>9,10</sup> Further, as recommended by the Centers for Disease Control and Prevention, ethambutol should be discontinued once drug-susceptibility tests show it to be unnecessary.<sup>10</sup>

Several other agents less clearly toxic to the optic nerve are carbon disulfide, chloramphenicol, pheniprazine, quinine, and thallium. In addition, toxins such as carbon tetrachloride, cassava, dapsone, and suramin are suspected but unproven causes of optic neuropathy.<sup>22</sup>

**Fig. 9.9.1 Humphrey Visual Field Strategies 30–2.** A large stimulus V was used. (A) Note the centrocecal scotoma that bridges fixation to the blind spot of the right eye. (B) In the left eye, the scotoma seems a little more centralized around fixation. It is notable that this patient, who had tobacco–alcohol amblyopia (mixed toxic and nutritional deficiency optic neuropathy), also had relatively small central scotomas but visual acuities of 20/400 (6/120) in each eye.

**Fig. 9.9.2 Fundus Views Reveal Mild Temporal Optic Disc Pallor.** (A) Right optic disc. (B) Left optic disc. More interesting, however, is the loss of the nerve fiber layer in the papillomacular bundle. This patient, who had tobacco–alcohol amblyopia (mixed toxic and nutritional deficiency optic neuropathy), also had visual acuities of 20/400 (6/120) in each eye, which recovered to only 20/100 (6/30) after changes in habit and diet and vitamin therapy. In this class of optic neuropathies, relatively severely compromised visual acuities and dyschromatopsia often are found with minimal optic disc atrophy.

Similarities in clinical presentations of nutritional and toxic optic neuropathies are likely due to perturbation of the common biochemical pathway responsible for energy metabolism within the optic nerve head. Oxidative phosphorylation within mitochondria involves the process of electron transfer to oxygen and the production of ATP. Vitamins such as B12 and folic acid are crucial to this process. Similarly, agents such as cyanide or formate (a metabolic product of methanol) block this electron transport. The final common product of these deficiencies and toxins is decreased ATP production by mitochondria and the accumulation of ROS.<sup>2,5</sup> Compensatory mechanisms may apply to some cell types, but fibers of the optic nerve—most particularly the PMB—are susceptible due to the long unmyelinated segment in the retina and the consequent inefficiency of unmyelinated axonal conduction.<sup>25</sup>

## OCULAR MANIFESTATIONS

LHON typically begins with the sudden onset of painless monocular visual loss, which the patient may describe as a blurring of vision, but more often as a central dark or gray cloud. This develops first in one eye and then soon after (days to several weeks) afflicts the fellow eye in a similar fashion. In contrast, most patients who have either toxic or nutritional optic neuropathy experience slowly progressive bilateral loss of central vision. Described

below are the ocular manifestations that on the whole are quite similar for all three syndromes (LHON, nutritional, and toxic optic neuropathies).

On examination, patients generally have bilateral impairment of visual acuity that varies from minimal to hand motion vision. The severity of visual acuity loss in the two eyes is usually quite symmetrical. Loss of color vision is more profound than the loss of visual acuity. Very early cases may exhibit isolated dyschromatopsia.<sup>26</sup> The hallmark of these disorders is the visual field defect that consists of a centrocecal scotoma that begins nasal to the blind spot and extends to involve fixation on both sides of the vertical meridian (Fig. 9.9.1). Pupillary reactions are often normal, even in the early monocular stages of LHON. This is because of a relative preservation of the melanopsin retinal ganglion cells that subserve the retinotectal pathway in LHON.<sup>27–29</sup>

A peripapillary microangiopathy may occur in early LHON.<sup>30</sup> Telangiectatic or tortuous blood vessels may be seen around the optic disc, but this occurs transiently and often is overlooked until involvement of the second eye becomes apparent. In nutritional deficiencies and toxic optic neuropathies, the fundus may appear normal. However, a careful examination may reveal nerve fiber layer losses in the PMB, sometimes associated with swelling of the nerve fiber layer in the arcuate bundles above and below the denuded area.<sup>31</sup> Later in the course of the disease, the temporal optic nerve pallor is often noted (Fig. 9.9.2). The mismatch between relatively

mild temporal disc pallor and severe depression of visual acuity, visual field, and color vision may lead to the misconception that the patient is malingering.

## DIAGNOSIS AND ANCILLARY TESTING

A careful history usually provides enough information to make a presumptive diagnosis of LHON. The patient describes the subacute, painless loss of vision monocularly, possibly followed soon after by involvement of the fellow eye. This sequential involvement and the family history help to differentiate LHON from nutritional deficiencies and toxic optic neuropathies. Most often, LHON manifests in men in their late teens or early twenties. It can be differentiated from toxic and nutritional optic neuropathies by the family history, presence of telangiectatic vessels around the optic nerve head during the acute phase, and the likelihood that one eye is affected before the other (not simultaneous occurrence). Optical coherence tomography (OCT) will reveal peripapillary nerve fiber layer thickening early in the disease course followed by thinning as atrophy ensues, while the ganglion cell complex will show progressive atrophy (see Chapter 9.2). The diagnosis is confirmed by laboratory study of the point mutation in the mitochondrial DNA.

Care must be taken to explore all possibilities in terms of diet, medications, and exposures, with an emphasis on recent changes in pattern. Suspected toxicities can be confirmed through serum and urine analysis. In particular, 24-hour urine collection for heavy metal screening may yield unexpected results. In addition to serum vitamin levels for B1, B2, B12, and folic acid, it is often useful to obtain serum pyruvate levels.

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis of toxic and nutritional optic neuropathies includes disorders that cause acute and subacute symmetrical losses in visual acuity and color vision. The similarities between LHON and nutritional deficiency and toxic optic neuropathies have been addressed.

Autosomal dominant optic atrophy (DOA), a nuclear (OPA1) genetic disorder, can be confused with toxic and nutritional optic neuropathies. There is an autosomal dominant family history, and the optic neuropathy occurs slowly and progressively in late childhood.

Chiasmal syndromes sometimes need to be ruled out. Pituitary adenomas or other lesions that compress the optic chiasm generally present with bitemporal visual field loss but without any significant loss of central acuity or color vision. In the early stages, bitemporal field losses may appear similar to centrocecal scotomas, particularly with prefixed chiasm. Occasionally, optic neuritis may occur bilaterally and produce almost any type of visual field defect. If the patient has multiple sclerosis, a number of plaques may be visible on T2-FLAIR sequences in magnetic resonance images; furthermore, most patients who have optic neuritis show dramatic recovery of visual acuity over several weeks.

There is controversy regarding the possibility that amiodarone may cause optic neuropathy. Amiodarone is a benzofuran derivative with vasodilatory and antiarrhythmic properties, used in treating supraventricular and ventricular cardiac arrhythmias. Among the numerous side effects, ranging from mild to life threatening,<sup>32</sup> corneal microdeposits are very common and can even be used to ascertain the therapeutic dosage of the therapy. The keratopathy usually does not cause any serious visual disturbance, but occasionally patients may note halos and mild photosensitivity.<sup>33</sup> Hyperthyroidism, peripheral neuropathy, ataxia, bone marrow depression, and pulmonary toxicity are several of the more severe side effects that are attributed to the use of amiodarone.<sup>32,34</sup>

Some reports suggest that patients on amiodarone therapy may also be at risk of developing an amiodarone-induced optic neuropathy, which is hard to distinguish from nonarteritic anterior ischemic optic neuropathy (AION). The most compelling evidence for the existence of amiodarone-induced AION is the increased incidence of AION among patients receiving amiodarone therapy (1.79%).<sup>35</sup> This is higher than the incidence of AION in the general population age 50 or older (0.3%).<sup>35</sup> However, such a comparison fails to consider that patients on amiodarone therapy have cardiac arrhythmias, hypertension, and other potential risk factors for AION.

Others have suggested that amiodarone produces an optic neuropathy that can be distinguished from AION. Purported amiodarone-induced optic neuropathy may be characterized by the insidious onset of bilateral and symmetrical visual loss with slow progression, whereas AION is characterized by an acute, unilateral visual loss that is rarely progressive. Amiodarone-induced optic neuropathy causes a protracted disc swelling

that tends to stabilize within several months of discontinuation of medication, whereas AION is characterized by resolution of disc edema over several weeks. In amiodarone-induced optic neuropathy, the cup-to-disc ratio is larger than that seen in AION,<sup>35</sup> and the fundus should exhibit bilateral disc edema (Fig. 9.9.3).

Nonetheless, it may be prudent to perform ophthalmological examinations on patients taking amiodarone. Alternative antiarrhythmic therapy may be considered in cases of bilateral disc edema. While a relationship between LHON and AION is tenuous, mitochondrial dysfunction has the potential to underlie a variety of optic neuropathies.<sup>36</sup>

Finally, because the nerve and nerve fiber layer changes in LHON and nutritional and toxic optic neuropathies can sometimes be very subtle, psychogenic visual loss often is considered in the differential diagnosis. Electrophysiological studies can be useful to distinguish organic from inorganic disease (see Chapter 9.27).

## SYSTEMIC ASSOCIATIONS

Multifactorial mixed nutritional optic neuropathies may be associated with neurological symptoms, such as paresthesias, ataxia, or hearing impairment, in addition to visual involvement. However, these are more characteristic of general nutritional deficiencies sometimes found in clusters in equatorial countries and termed tropical amblyopias. These instances are not usually described in cases of toxic exposure or single vitamin deficiency.<sup>37</sup> Visual symptoms may be seen in association with paresthesias and dysesthesias—particularly in the legs—in association with ataxia and hearing loss. This has been described in vitamin deficiencies associated with poor diet, compounded by the ingestion of cassava and by elevated levels of cyanide.<sup>38</sup>

## PATHOLOGY

Much of our understanding of pathology that underlies hereditary optic neuropathies comes from the study of LHON. The discovery of the ND4 mutation by Wallace's group<sup>39</sup> in 1988 opened the door to understanding the complex interplay between mitochondrial and nuclear DNA that underlies energy production in living cells.<sup>39</sup> Sadun et al.,<sup>25</sup> Kerrison et al.,<sup>40</sup> and others have since provided ultrastructural characterizations of the three primary mitochondrial mutations in LHON from genetically characterized pedigrees.<sup>41,42</sup> In addition to severe losses of retinal ganglion cells in the macular area and depletion of the nerve fiber layer, these authors described accumulations of mitochondria in other orbital tissues and noted electron-dense,<sup>43</sup> membrane-bound calcium inclusions in the remaining retinal ganglion cells. These diseased mitochondria appear to be unable to produce as much ATP, but perhaps more significantly, there is an increase in reactive oxygen species (ROS) production.<sup>44</sup> This ultimately leads to the death of the cell.

Clinically there are two stages to LHON, carriers who have the mutation and have "normal vision" and affected patients who have the mutation and vision loss. This distinction is perhaps an artifact of our ability to detect changes in asymptomatic carriers. Objective tests such as OCT measurements do show subclinical changes in the optic nerve.<sup>43</sup>

Savini and coworkers<sup>45</sup> have provided further objective evidence that in subclinical LHON, the PMB is affected as shown by the significant increase in RNFL thickness observed by OCT measurements in the temporal quadrant. A thickening of the temporal fibers was detected in all subgroups of unaffected carriers with males having a more diffuse involvement than females. Unaffected male carriers showed a thicker RNFL in the temporal and inferior quadrants and in the 360° average measurement. Unaffected female carriers had an increased thickness in the temporal quadrant when compared with the control group.<sup>45</sup>

These data suggest that the RNFL swells especially in the PMB in the presymptomatic stage of LHON. RNFL thickening of these fibers suggests that selective injury with swelling of RNFL occurs before atrophic changes are established. This offers clinicians the opportunity to more carefully track LHON development in patients in the presymptomatic stage. LHON may manifest with a subclinical phase with axonal thickening and near normal visual function that may or may not precede clinically significant vision loss reflecting the acute phase of axonal injury with clinically significant loss of visual function.

Hence, we are in a paradigm shift in regard to LHON. No longer should we consider this as a disease in which phenotypically normal carriers abruptly transition to affected status. Rather, there may be a complex interplay between compensatory and decompensatory factors that may also represent a window of opportunity for treatment.<sup>46</sup>

**Figure 9.9.3 Fundus Views From a Patient With Amiodarone-Associated Optic Neuropathy.** The patient presented with constricted visual fields and bilateral simultaneous disc swelling (A–B) that resolved with the discontinuation of amiodarone (C–D).

Much of what we have learned about LHON has implications for the other hereditary, nutritional, and toxic optic neuropathies.<sup>47,48</sup> One of the better understood outbreaks of optic neuropathies occurred in Cuba in the early 1990s (CEON). Socioeconomic challenges led to malnutrition, which combined with high levels of tobacco and cassava consumption increased circulating levels of cyanide. The toxicity of cyanide on the mitochondria is well described and indeed most toxic or nutritional optic neuropathies affect mitochondrial energy production leading to cell death.<sup>48,49</sup> Some agents, such as antibiotics, are targeted to enzymes that lead to the death of microorganisms. Mitochondria are in essence bacteria that are living in eukaryotic cells.<sup>50</sup> Thus it is not surprising that antimicrobials, including ethambutol, linezolid, and erythromycin, are able to cause a mitochondrial optic neuropathy by poisoning the energy production of the cells.<sup>51</sup>

The most intriguing aspect of the pathophysiology of all of these optic neuropathies is their preference for the papillomacular bundle. This can, also, be explained by the energy dynamics of the cells involved. RGCs are in part more susceptible to injury than other neurons as they have a long unmyelinated segment and high energy demands. The fibers of the PMB, which subserve the central vision, are the most susceptible RGCs as they have a narrow caliber leading to a relatively high surface area to volume ratio.<sup>2,13,14,52</sup> This, in turn, increases their energy needs and paradoxically limits their ability to compensate for the increased energy demands of defective mitochondria by physically limiting the ability to accumulate more mitochondria.<sup>51</sup> This compensatory accumulation of mitochondria accounts for the electron-dense bodies found in LHON described above.

## TREATMENT

The cause of a toxic or deficiency optic neuropathy should be found and treated early (for example, by cessation of smoking and the administration of vitamins in tobacco–alcohol amblyopia). In the absence of a demonstrable deficiency, no good evidence exists that empirically giving B vitamins is of any benefit. Nonetheless, it is not uncommon to prescribe cyanocobalamin (vitamin B12) in suspected cases of tobacco–alcohol amblyopia and LHON. Idebenone, a quinol analog, has been used recently in a few cases of LHON to ameliorate the net ATP synthesis by providing an alternate pathway, as well as scavenging free radicals with the advantage of concentrating readily in the mitochondria.<sup>53</sup> Patients who have already lost vision in one eye from LHON might be candidates for pharmacological manipulation of mitochondrial metabolism to protect the second eye.<sup>13,36</sup>

Coenzyme Q10 has been proposed as treatment for LHON as it can target the excessive production of ROS. However, there have been no successful case series with this treatment, which is not surprising given the lack of blood–brain barrier penetration by CoQ10.<sup>14</sup> Second (idebenone) and third (EPI-743) generation quinones with better blood brain barrier penetration have been used with greater success.<sup>54–56</sup> These treatments are neither dramatic nor quick to show effect. However, after 1 year of quinone treatment, most patients show some improvement.<sup>54–56</sup>

Other treatment approaches under investigation for LHON include different methods of supporting the electron transport chain stabilization and reducing ROS,<sup>57–59</sup> and new approaches using gene therapy. The

first involves the use of adenovirus-associated vectors (AAV2) to supplement the defective mitochondrial DNA gene product with the unmutated form. Data from animal and preliminary human studies suggest that this treatment approach could correct the underlying genetic defect.<sup>60-63</sup> The second genetic approach seeks to eradicate LHON by replacing the damaged mtDNA with wild-type mtDNA prior to conception. This technology, termed mitochondrial donation, inserts a donor oocyte with wild type mtDNA (which is enucleated and has the nuclear DNA of a woman carrying the mtDNA mutation).<sup>64</sup> There is considerable ethical debate on the future of this therapy,<sup>65</sup> and experimentation with this technology is limited. An adapted approach exploits the presence of both mutant mtDNAs in the oocyte prior to conception and attempts to skew the heteroplasmy in favor of the wildtype.<sup>66</sup> All of these techniques are still investigative and have implications not only for LHON but also other genetic disorders.<sup>47</sup>

## COURSE AND OUTCOME

In many cases, prompt administration of the deficient nutrient (such as a vitamin) or removal of the toxin (such as ethambutol) results in significant recovery over a period of months. However, in cases in which the injury is long-standing, there may be little or no recovery. In LHON, most patients show minimal recovery, although there have been reports of dramatic and late improvements in individuals carrying the 14484 mutation.<sup>67</sup> The 11778 and 3460 mutations carry a less favorable prognosis, with over 75% becoming legally blind in both eyes.<sup>13</sup> Advances with quinone therapy, such as idebenone, have altered the natural history of LHON, often contributing to stabilization of vision and sometimes modest recovery.<sup>54-56</sup> Advances in the genetic therapies, if successful, have the promise to both treat affected carriers and stop germline transmission of LHON-mutated mtDNA.

# Prechiasmal Pathways—Compression by Optic Nerve and Sheath Tumors

9.10

Michelle Y. Wang, Thomas C. Spoor

**Definition:** Optic nerve dysfunction occurring as a result of compression by a space-occupying lesion, typically tumor or aneurysm, anywhere along the nerve's course from globe to chiasm.

## Key Features

- Progressive visual field deterioration.
- Relative afferent pupillary defect.
- Dyschromatopsia.

## Associated Features

- Proptosis.
- Swollen or atrophic optic disc.
- Retinal and choroidal striae.
- Optociliary collateral vessels.
- Venous stasis retinopathy or central retinal vein occlusion.

## INTRODUCTION

The optic nerve extends from the back of the eye, traverses the orbit, passes through the optic canal, and has a variable intracranial course before it joins with the contralateral optic nerve to form the chiasm (Fig. 9.10.1). Compression by a tumor or an aneurysm may cause optic nerve dysfunction anywhere along its course from globe to chiasm.

Extrinsic optic nerve compression by orbital tumors or apical orbital compression by enlarged dysthyroid extraocular muscles represents an uncommon but potentially treatable cause of optic neuropathy. These tumors may compress the optic nerve at the orbital apex (Fig. 9.10.2).

## EPIDEMIOLOGY AND PATHOGENESIS

Compression of the apical orbital optic nerve by enlarged extraocular muscles is an uncommon manifestation of thyroid orbitopathy (Fig. 9.10.3). The vast majority of patients who have hyperthyroidism have mild,

noninfiltrative orbitopathy. Clinically significant infiltrative orbitopathy occurs in only 3%–5% of the hyperthyroid population.

Encapsulated orbital tumors are quite uncommon. Of these, cavernous hemangiomas are the most common, neurilemmomas are less common, and hemangiopericytomas are even rarer.

## OCULAR MANIFESTATIONS

Initially, extrinsic optic nerve compression within the orbit manifests with slowly progressive loss of visual acuity, decreased brightness sensation, and dyschromatopsia. Vision may be good at presentation, but visual field deterioration and relative afferent pupillary defect are seen with progression.

**Fig. 9.10.1** Axial Cadaver Section That Demonstrates the Course of the Optic Nerve From the Globe to the Optic Chiasm. Note the intraorbital, intracanalicular, and intracranial segments of the optic nerve.

**Fig. 9.10.2** Images of a Large Orbit Mass Adjacent or Contiguous With the Optic Nerve. (A) Computed tomography scan (axial). (B) Magnetic resonance imaging shows obvious demarcation between the tumor and the adjacent optic nerve.

**Fig. 9.10.3 Computed Tomography Scans (Axial and Coronal).** The optic nerves are compressed at the orbital apex by enlarged extraocular muscles.

Patients who have large tumors with more anterior optic nerve compression may have a swollen optic disc and choroidal striae. However, anterior orbital tumors more commonly occur with proptosis without compressive optic neuropathy. In patients with thyroid orbitopathy, manifestations such as eyelid retraction and extraocular motility restriction may be seen.

## DIAGNOSIS AND ANCILLARY TESTING

It is key to obtain appropriate imaging studies to visualize the orbital apex. Computed tomography (CT) scanning differentiates optic nerve compression by orbital tumors from apical orbital optic nerve compression by enlarged, dysthyroid extraocular muscles (see Fig. 9.10.2). Magnetic resonance imaging (MRI) scans can help delineate the extent of orbital tumor and facilitate surgical management. Ocular coherence tomography (OCT) may be useful to detect early loss of peripapillary retinal nerve fiber layer (see Chapter 9.2).

## TREATMENT

Treatment of dysthyroid optic neuropathy is to decompress the orbit (more details are discussed in Chapter 12.13). Inflammation may be reduced with systemic corticosteroids or low-dose irradiation, and the orbital apex may be expanded by surgical removal of the orbital walls. In a recent survey, most surgeons prefer a combined approach of floor and medial wall decompression or lateral and medial wall decompression.<sup>1</sup> We favor the initial use of systemic corticosteroids, either intravenous or high-dose oral prednisone 80 mg daily, followed by orbital decompression. Orbital irradiation is reserved for cases refractory to corticosteroids and surgical decompression.

Treatment of optic nerve compression caused by an encapsulated orbital tumor entails surgical removal of the tumor. MRI may help to differentiate the tumor from the optic nerve and ascertain the tumor's position in reference to the optic nerve. The latter is important in planning an appropriate surgical approach for tumor excision.

## OPTIC NERVE COMPRESSION BY OPTIC NERVE AND SHEATH TUMORS

### INTRODUCTION

The optic nerve may be invaded by intrinsic tumors (such as gliomas) arising from the neuroglia or neurons or compressed by extrinsic tumors arising from the meninges (such as meningiomas). Optic nerve gliomas and optic nerve sheath meningiomas are the most common tumors to involve the optic nerve. Less commonly, the optic nerve also may be involved by lymphomas, leukemias, malignant gliomas, and metastatic cancers.

## GLIOMAS AND MALIGNANT GLIOMAS

### Epidemiology and Pathogenesis

Gliomas of the anterior visual pathways are the most common tumors of the central nervous system, accounting for 2% of all gliomas and 5% of

**Fig. 9.10.4 Magnetic Resonance Imaging of a Large Optic Nerve Glioma and Optic Canal.**

childhood gliomas. These tumors occur most commonly during the first two decades of life; 65% occur within the first decade, and 90% occur before 20 years of age. Rarely, a glioma may occur in a previously asymptomatic adult as an expanding orbital mass. Gliomas of the anterior visual pathways account for 65% of all intrinsic optic nerve tumors.<sup>2</sup> Malignant gliomas of the optic nerve are rare.<sup>3,4</sup> Gliomas that involve the intraorbital optic nerve are most common (47%). Those that involve the orbital and intracranial optic nerve are second most common (26%), followed by intracranial and chiasmal involvement (12%) and gliomas confined to the optic chiasm (5%).<sup>4</sup>

## Ocular Manifestations

Patients with optic nerve gliomas usually experience exophthalmos, extraocular motility dysfunction, decreased visual function, and dyschromatopsia accompanied by a relative afferent pupillary defect. The optic disc may be normal, swollen, or atrophic. Central retinal vein occlusion may occur.

Patients who have malignant gliomas of the optic nerve have rapidly progressive, painful visual loss accompanied by signs of an optic neuropathy.<sup>3,4</sup> Initial visual loss may be unilateral or bilateral (chiasmal involvement), but rapid progression to bilateral blindness and death are constant features.<sup>2</sup>

## Diagnosis

Intrinsic enlargement of the optic nerve on MRI is evident in patients who have optic nerve gliomas. The presence and extent of optic nerve gliomas is best demonstrated by MRI (Fig. 9.10.4).<sup>2</sup> Although rarely missed with high-resolution CT scans, optic nerve enlargement by an intrinsic glioma may be confused with compression by a resectable orbital tumor; MRI may help to differentiate these (see Fig. 9.10.3).

For patients who have orbital nerve gliomas and neurofibromatosis type 1, MRI demonstrates a typical double-intensity tubular thickening caused by perineural arachnoid gliomatosis and elongation and downward kinking of the midorbital optic nerves.<sup>5</sup>

Imaging studies of an optic nerve glioma may show enlargement of the optic forearm that arises from secondary meningeal hyperplasia. Therefore, enlargement of the optic forearm is not firm evidence of intracranial extension of an optic nerve glioma.

Imaging studies of malignant gliomas of the optic nerve demonstrate enlargement of the involved regions of the optic nerve and chiasm, although initially normal imaging study results have been reported.<sup>3,4</sup> The diagnosis of this devastating disease should be confirmed by biopsy of the involved portion of the optic nerve.

## Differential Diagnosis

The differential diagnosis of visual loss from optic nerve glioma is the differential diagnosis of any slowly progressive optic neuropathy. Differentiation between gliomas and other causes of optic nerve compression in a child is best accomplished using appropriate imaging studies (see earlier).

## Systemic Associations

Frequently, optic nerve gliomas are found in association with neurofibromatosis type 1 (only rarely with neurofibromatosis type 2), which is present in 25% of patients who have optic nerve gliomas, whereas 15% of patients with neurofibromatosis have optic nerve gliomas. Increased intracranial pressure and chiasmal and optic tract involvement are more common in patients who do not have neurofibromatosis. Precocious puberty is more common in children who have gliomas and neurofibromatosis.<sup>6,7</sup>

## Pathology

Optic nerve gliomas are intrinsic tumors that arise from the neuroglia—usually astrocytes but occasionally oligodendrocytes. Three histopathological patterns exist:

- Transitional areas in which the tumor merges with normal optic nerve and which may be difficult to differentiate from reactive gliosis.
- Areas of tumor necrosis, which may appear as cystic spaces that contain reticulated, myxomatous material.
- Areas where astrocytes may show spindle cell formation and contain cytoplasmic, eosinophilic structures called Rosenthal fibers.

These patterns are characteristic but not diagnostic of optic nerve gliomas.<sup>6</sup> Arachnoid hyperplasia, secondary to infiltration by the glioma through the pia, may mimic an optic nerve sheath meningioma.

Biopsy specimens of malignant gliomas of the optic nerve demonstrate bizarre, atypical malignant astrocytes that separate disrupted myelin sheaths.

## Treatment

Treatment of gliomas of the anterior visual pathways is controversial. If visual function is good, isolated intraorbital optic nerve gliomas may be observed. Visual function may be followed with serial visual field testing, and MRI should be done every 6–12 months to detect any intracranial extension. Most of those tumors grow slowly over time and may be self-limited. Since most observed patients retain stable vision, surgery is rarely necessary.<sup>8</sup> If vision is poor or exophthalmos is excessive and unsightly, the lesion may be removed via a craniotomy and superior orbitotomy. If intracranial extension by a glioma initially confined to the orbit is documented, the tumor can be removed completely via craniotomy in an effort to avoid chiasmal, hypothalamic, or third ventricle involvement. Chemotherapy has increasingly become the initial treatment for infants with optic pathway gliomas as it may help defer radiotherapy until the child has completed development.<sup>9</sup> Radiotherapy may be helpful for tumors involving the chiasm or optic tract. It may also be considered as an adjuvant therapy after surgery or chemotherapy if there is progressive growth in the chiasm. However, radiotherapy is accompanied by a significantly increased risk of second nervous system tumors in patients with neurofibromatosis type 1 as well as growth retardation in infants.<sup>10</sup>

There is no successful treatment for malignant gliomas of the visual pathways.

## Course and Outcome

Optic nerve gliomas are true neoplasms that characteristically demonstrate early growth followed by long periods of stability in many cases. They have a poor prognosis for vision, but if the tumor is confined to the optic nerve, long-term survival is excellent. If the chiasm, hypothalamus, or third ventricle is involved, the prognosis for life diminishes. Once the hypothalamus is involved, mortality rises to over 50%. No therapy exists of proven benefit.<sup>3</sup> Spontaneous regression may occur.<sup>11</sup> There is a tendency for vision in the worse eye to deteriorate and vision in the better eye to remain stable regardless of treatment or neurofibromatosis status.<sup>12</sup>

Patients who have malignant gliomas of the optic nerve experience painful visual loss and rapidly progress to bilateral blindness within 6–8 weeks. Death invariably follows within 6–9 months after the initial symptoms.<sup>3,4</sup>

## OPTIC NERVE SHEATH MENINGIOMAS

### INTRODUCTION

Meningiomas are benign neoplasms that arise from the meningotheelial cells of the meninges. The optic nerve may be compressed by meningiomas

**Fig. 9.10.5** Gadolinium-Enhanced Magnetic Resonance Imaging Demonstrates the Intracranial Extension of an Optic Nerve Sheath Meningioma.

confined to the optic nerve or by orbital extension of intracranial tumors. Slowly progressive, relentless visual loss may be accompanied by proptosis and extraocular motility dysfunction.

## EPIDEMIOLOGY AND PATHOGENESIS

Optic nerve sheath meningiomas represent 1%–2% of all meningiomas. After gliomas, these are the second most common type of optic nerve tumor and primarily affect middle-aged adults, usually women.

## OCULAR MANIFESTATIONS

Slowly progressive visual loss is the hallmark of an optic nerve sheath meningioma. Some patients may present with transient vision loss, which may be gaze evoked. A relative afferent pupillary defect and dyschromatopsia invariably are present. The optic disc may be swollen or atrophic. Retinal and choroidal folds may be evident on fundus examination. Even though optociliary collateral vessels may not always be present, their presence indicates chronic compression of the central retinal vein. Extraocular motility dysfunction is present in some cases.

## DIAGNOSIS

Neuroimaging confirms the diagnosis of optic nerve sheath meningioma. CT scans demonstrate fusiform, tubular, or irregular enlargement of the optic nerve. The borders of the enlarged optic nerve may enhance after administration of intravenous contrast to leave a central, linear lucency within the optic nerve sheath (tram-track sign). Extensive or segmental calcifications also may be present.

MRI fat suppression and gadolinium-diethylenetriamine-pentaacetic acid (Gd-DTPA) enhancement can detect and demarcate precisely the degree of extension of optic nerve sheath meningiomas (Fig. 9.10.5). The majority of intraorbital and intracranial meningiomas are detectable by CT scans, but gadolinium-enhanced MRI can more reliably demonstrate subtle findings (see Fig. 9.10.5). Rarely, isolated small intracanalicular tumors may still be difficult to visualize. Studies with high-quality MRI demonstrate that even with small tumors, intracranial extension is the rule rather than the exception.<sup>13</sup>

## PATHOLOGY

Meningiomas arise from the meningotheelial cells of the arachnoid villi. Histopathology demonstrates patterns of whorls and sheets of meningotheelial cells. A variable amount of fibrous and vascular tissue occurs in fibroblastic pattern meningiomas, with psammoma bodies present in psammomatous and mixed meningiomas.

## TREATMENT

The management of optic nerve sheath meningioma is controversial. Traditionally, treatment is conservative because these tumors tend to grow

very slowly and are not amenable to complete resection without compromising the vascular supply due to its close proximity to the optic nerve and pial vasculature. Most tumor resections result in complete visual loss, except for tumors that are primarily extradural.<sup>14</sup> Therefore, observation, serial automated visual fields, and MRI scans are appropriate for patients who have good vision without evidence of intracranial extension of tumor. In patients who have no useful vision, surgery is warranted when there is intracranial extension or to relieve severe disfiguring exophthalmos. For patients who still have useful vision, surgery should be limited to the intracranial portion.

Conventional radiotherapy can be successful<sup>15</sup>; however, radiation-associated complications limit its use. Stereotactic or conformal fractionated radiotherapy, designed to deliver more focused radiation, allows a high degree of spatial specificity to the tumor. This new technique shows promise in improving long-term visual outcome and minimizing irradiation of the surrounding tissue.<sup>16,17</sup> Stereotactic and conformal fractionated radiotherapy are becoming accepted as the treatments of choice when patients demonstrate progressive vision loss. It is important to maintain long-term follow-up as radiation-induced pathology, including secondary neoplasia, remains a potential risk.

## COURSE AND OUTCOME

The clinical course of optic nerve sheath meningiomas is a slowly progressive, relentless visual loss in the affected eye. The prognosis for life is excellent, with an overall tumor-related mortality of near zero.<sup>14</sup>

## OTHER INTRACANALICULAR AND INTRACRANIAL COMPRESSIVE LESIONS

The optic nerves may be compressed within the optic canal or intracranially by any entity that can compress the optic chiasm, depending on the length of the intracranial optic nerves and their position relative to intracranial structures (e.g., pre- or post-fixed optic chiasm; see Chapter 9.12). Aneurysms, tumors, infection, inflammation, mucocoeles, and processes that involve the sphenoid bone, such as fibrous dysplasia, may cause a compressive optic neuropathy (Box 9.10.1). The involved optic nerves may appear normal, atrophic, swollen, or excavated. Optic disc excavation in the absence of elevated intraocular pressure may indicate a compressive optic neuropathy, especially if accompanied by pallor of the neuroretinal rim.<sup>14</sup>

# Traumatic Optic Neuropathies

Michelle Y. Wang, Thomas C. Spoor

# 9.11

**Definition:** Optic nerve damage after cranio-orbital trauma.

## Key Features

- Decreased visual acuity.
- Visual field defects.
- Relative afferent pupillary defect.

## Associated Features

- Optic nerve infarction.
- Orbital or optic nerve sheath hematoma.
- Central retinal artery occlusion.
- Orbital and optic canal fractures.

## INTRODUCTION

Optic neuropathy may occur directly or indirectly after cranio-orbital trauma. Causes of damage include optic nerve transection, avulsion, ischemia, or orbital hemorrhage and edema. Direct optic nerve injuries arise from penetrating trauma, especially orbital fractures associated with mid-facial fractures, whereas indirect optic nerve injuries occur when the force of impact is imparted into the skull and transmitted to the optic nerve. Orbital hemorrhage compromises the circulation to the optic nerve, resulting in injury secondary to orbital compartment syndrome. Primary injury to the optic nerve fibers by transection or infarction at the time of injury results in permanent damage. However, neural dysfunction secondary to compression within the optic canal as a result of edema and hemorrhage may respond to medical or surgical intervention.

## EPIDEMIOLOGY AND PATHOGENESIS

Traumatic optic neuropathy (TON) occurs in 0.5%–2% of patients who suffer closed head trauma.<sup>1</sup> The optic nerve is enclosed tightly within the bony optic canal; it may be damaged by shearing and avulsion of its nutrient vessels or by pressure transmitted along the bone to the optic canal.

## OCULAR MANIFESTATIONS

A complete history is essential in the diagnosis of TON, which remains a clinical diagnosis. Visual acuity is invariably reduced, often to a significant degree, and is invariably accompanied by an afferent pupillary defect in cases of unilateral optic nerve injury. Patients who have bilateral and symmetric optic nerve dysfunction may demonstrate light-near dissociation, characterized by poor pupillary light responses but intact accommodative pupillary responses. Anterior injuries may cause avulsion of the optic nerve head, appearing as a ring of hemorrhage or a deep pit at the site of injury, as well as compromised retinal circulation resulting in infarction, hemorrhage, or central retinal artery occlusion evident on ophthalmoscopy. More posterior injuries often lead to an afferent pupillary defect and visual loss despite a normal fundus.

## DIAGNOSIS AND ANCILLARY TESTING

Visual fields may help localize the site of optic nerve damage, but testing of visual fields requires a sufficient level of vision, and there is no

pathognomonic field defect in TON. High-resolution computed tomography (CT) is the diagnostic procedure of choice as it can delineate bony fractures better than magnetic resonance imaging (MRI). Treatable causes of optic nerve compression, such as orbital and optic nerve sheath hemorrhages, are detected using CT scans,<sup>1</sup> as are orbital and optic canal fractures. MRI is superior to CT for imaging soft tissues and assessing chiasmal damages. Hyperintensity of the optic nerve on diffusion-weighted image due to restricted diffusion may be an imaging marker for TON.<sup>2</sup>

## DIFFERENTIAL DIAGNOSIS

Traumatic optic nerve injury may sometimes occur even after a relatively minor head injury. Detection of visual loss may be coincident with the traumatic event. The differential diagnosis should include other causes of optic neuropathies and causes of obviously treatable optic nerve compression (Box 9.11.1).

## PATHOLOGY

The optic nerve can be injured anywhere along its course, most commonly at the intracanalicular and intracranial portion. Forces applied to the frontal bone may be transmitted and concentrated at the optic canal.<sup>3</sup> Acceleration and deceleration forces may cause a partial or total avulsion of the retrobulbar optic nerve, contusion necrosis, and shearing of the pial vascular supply to the intracanalicular optic nerve leading to ischemic infarction. The bony canal has very limited space; the middle part of the canal is the narrowest segment, making it the most likely site of injury. Hence even a tiny amount of hemorrhage or swelling may cause optic nerve compression.<sup>4</sup> Orbital hemorrhage or hemorrhage into the optic nerve sheath also may cause progressive visual loss. The intracranial optic nerve may be injured by the falciiform dural fold caused by the force of a shifting brain at the moment of impact. Swelling of the intracanalicular optic nerve causes delayed, progressive visual loss through exacerbation of the ischemic effects of the original injury. Any or all of these mechanisms may be responsible for optic nerve injury.<sup>1</sup>

Optic nerve injuries may be caused by primary or secondary mechanisms. The primary mechanism causes mechanical shearing of the optic nerve and its vasculature, leaving permanent, irreparable damage to the optic nerve. Treatment modalities are potentially effective only for secondary mechanisms, which arise from the force of impact, causing optic nerve swelling at the cellular level and ischemia that further compromises an injured optic nerve.<sup>1</sup> Treatment consists of attempts to limit secondary injury and salvage axons that survive the initial trauma.

### BOX 9.11.1 Differential Diagnosis of Traumatic Optic Neuropathy

- Optic nerve sheath hematoma
- Orbital hematoma
- Subperiosteal hematoma
- Coincident optic neuropathies
- Compression by tumor or aneurysm
- Optic nerve inflammation
- Orbital inflammation
- Sinusitis with orbital involvement
- Ischemic optic neuropathy
- Optic neuritis

## TREATMENT

The primary optic nerve injuries are not treatable. The secondary effects of the primary injury—edema and hemorrhage—may be treatable. Although orbital hemorrhage that compromises the optic nerve warrants immediate decompression by lateral canthotomy and cantholysis, there is no established standard of care for TON secondary to other causes. Patients may improve spontaneously without treatment.<sup>5</sup> However, many suffer severe permanent vision loss. Treatment for TON remains controversial.

Treatment with megadose corticosteroids was initially suggested based, in part, on the success attained in treatment of spinal cord injuries.<sup>6</sup> Treatment should begin within 8 hours of injury. Methylprednisolone 30 mg/kg is administered intravenously over 30 minutes followed by 15 mg/kg 2 hours later. This dosing regimen compensates for the rapid serum half-life of methylprednisolone. Treatment is continued with 15 mg/kg every 6 hours for 24–48 hours. If visual function improves, corticosteroids are tapered rapidly. Administered within 8 hours after injury, megadose corticosteroids have an antioxidant and membrane-stabilizing effect that limits secondary cell damage and increases microcirculatory perfusion.<sup>7</sup>

Some studies show that patients treated with corticosteroids or a combination of corticosteroids and optic canal decompression seem to have better visual prognosis than untreated patients.<sup>5,8–10</sup> Treatment with megadose corticosteroids seems to improve vision more quickly than treatment with high-dose intravenous corticosteroids, but there is no significant difference in the final visual outcome.<sup>11,12</sup> However, the Corticosteroid Randomization After Significant Head Injury (CRASH) trial showed increased mortality among patients with acute head trauma who were treated with high-dose corticosteroids.<sup>13</sup> Given the severity of potential adverse effect and lack of proven clinical efficacy, Steinsapir and Goldberg recommend against the use of corticosteroid in TON.<sup>14</sup>

Surgery is recommended by those who believe that prompt surgical decompression may expand tissue space and relieve compression of the optic nerve.<sup>8</sup> As with any surgical procedure, potential risks must be weighed against possible benefits.

It is important to keep in mind that the benefits of medical, surgical, or combined treatment options have not been clarified by randomized

controlled trial. Therefore, many prefer the safer approach—observation and use of corticosteroids only in selected cases.<sup>15</sup> The International Optic Nerve Trauma Study, the largest unbiased study to date, failed to demonstrate clear benefit for either corticosteroids or optic canal decompression. Hence, it is important to individualize therapy and communicate to the patients and family the uncertain benefits of procedures and the potential harmful side effects prior to initiating any treatment.

# Lesions of the Optic Chiasm, Parasellar Region, and Pituitary Fossa

9.12

Richard M. Rubin, Alfredo A. Sadun, Alfio P. Piva

**Definition:** Tumors and intracranial processes causing loss of vision and visual field due to involvement of the optic chiasm, its blood supply, or adjacent optic nerve or optic tract.

## Key Feature

- Typical binocular temporal field loss with respect to the vertical midline.

## Associated Features

- Cavernous sinus symptoms such as ocular motor nerve palsies, Horner's syndrome, trigeminal hypoesthesia, or pain.
- Endocrine dysfunction.
- Headache.
- Hydrocephalus.
- Involvement of surrounding structures results in endocrine dysfunction that arises from disruption of the hypothalamic–pituitary axis or in abnormalities of ocular motility, pupillary function, or facial sensation. These signs and symptoms are caused by injury of the cranial nerves or of ocular sympathetic nerves in the cavernous sinus.

## INTRODUCTION

The word chiasm derives from the Greek letter chi ( $\chi$ ) and in the visual system refers to the appearance of the junction of the two optic nerves where they join to allow the hemidecussation of nasal fibers to the opposite optic tracts and the direct passage of temporal fibers to the ipsilateral optic tracts. Thus all visual information supplied to both eyes from the right visual space is transmitted to the left cerebral cortex, and that supplied from the left visual space is transmitted to the right cerebral cortex.

The unique anatomy of the chiasm and its relationship to other major structures explains the characteristic patterns of visual loss and cranial nerve, neurological, and endocrine dysfunction seen here (Fig. 9.12.1).<sup>1</sup>

## Anatomy

The optic chiasm, a flattened structure, is situated about 10 mm above the pituitary gland, which rests in the sella turcica of the sphenoid bone. These structures are separated by a space called the suprasellar or inferior chiasmatic cistern. The chiasm is also contiguous with the anterior-inferior floor of the third ventricle at the base of the brain. The intracranial optic nerves exit from the optic foramen and rise with a tilt of as much as 45°. Although the chiasm usually hangs directly over the pituitary fossa of the sella turcica, as a result of variations in the lengths of the optic nerves, the chiasm could also have a prefixed (15%) or postfixed (5%) position. Relative to a normal chiasm position, a prefixed chiasm would have a more rostral location, or a somewhat closer-to-the-tuberculum sellae position than normal. A postfixed chiasm would have a more caudal position than normal chiasm or a somewhat closer-to-the-dorsum sellae position (Fig. 9.12.2).<sup>2–5</sup> The pituitary infundibulum, which arises from the hypothalamus (ventral diencephalon) behind the chiasm, extends downward to the posterior lobe of the pituitary (neurohypophysis). The anterior lobe of the pituitary (adenohypophysis) forms embryologically from Rathke's pouch, an embryological structure connected to the pharynx. The chiasm

**Fig. 9.12.1 Median Sagittal Section Through the Chiasm and Relationship of Chiasm to Neighboring Structures.** The optic chiasm is suspended above the pituitary gland and rests in the sella turcica of the sphenoid bone. It is surrounded by cerebrospinal fluid, except posteriorly where it borders the anterior-inferior wall of the third ventricle. (Adapted from Sadun AA, Rubin RM. *Developments in sensory neuro-ophthalmology*. In: Silverstone B, Lang MA, Rosenthal B, et al, editors. *The Lighthouse handbook on vision impairment and rehabilitation*. New York: Oxford University Press; 2000.)

is flanked laterally by the supraclinoid segments of the carotid arteries and inferolaterally by the cavernous sinuses (Fig. 9.12.3).<sup>5,6</sup> The arterial supply of the chiasm is derived from the anterior cerebral and anterior communicating arteries from above and posterior communicating, posterior cerebral, and basilar artery from below as the chiasm is located centrally at the circle of Willis (Fig. 9.12.4).<sup>7–9</sup> Although noted by Michel as early as 1887, Hermann Wilbrand described in several publications, starting in 1904, a group of crossing, inferior nasal quadrant, extramacular ganglion cell axons that loop anteriorly into the posterior portion of the contralateral optic nerve before they turn posteriorly and laterally to head into the optic tract (Wilbrand's knee).<sup>10</sup> In the early 1960s, Hoyt<sup>11–13</sup> and Luis<sup>11,12</sup> confirmed, in the primate chiasm, the presence of Wilbrand's knee and also demonstrated that the arrangement of axons within the optic chiasm is such that superior nasal quadrant retinal fibers remain superior and cross more posteriorly in the chiasm. They also showed that macular fibers cross through the chiasm in its central and posterior portions and that arcuate fibers maintain their relative superior or inferior position while they are passing through the chiasm (Figs. 9.12.5–9.12.7).

However, more recently, Horton<sup>14</sup> suggested that Wilbrand's knee is an artifact of the preparations studied.

## EPIDEMIOLOGY AND PATHOGENESIS

### Pituitary Adenomas

Chiasmal dysfunction most commonly occurs as a result of pituitary adenomas, which make up 12%–15% of symptomatic intracranial neoplasms.

**Fig. 9.12.2** Variation in the Length of the Optic Nerves Alters the Relative Position of the Chiasm to the Sellar Structures. Relative to a normal chiasm position, a prefixed chiasm would have a more rostral location or a somewhat closer-to-the-tuberculum sellae than normal. A postfixed chiasm would have a more caudal position than normal chiasm or a somewhat closer-to-the-dorsum sellae. (Adapted from Rhoton AL, Harris FS, Renn WH. Microsurgical anatomy of the sellar region and cavernous sinus. In: Glaser JS, editor. Neuro-ophthalmology: symposium of the University of Miami and the Bascom Palmer Eye Institute, vol. 9. St Louis: CV Mosby; 1977. p. 75–105.)

**Fig. 9.12.3** Coronal Section Through the Optic Chiasm and Cavernous Sinuses. The chiasm is flanked laterally by the supraclinoid segments of the carotid arteries and inferolaterally by the cavernous sinuses through which pass the oculomotor nerves and first two divisions of the trigeminal nerve. (Adapted from Warwick R. The orbital vessels. In: Warwick, R, editor. Eugene Wolff's anatomy of the eye and orbit. 7th ed. Philadelphia: WB Saunders; 1976. p. 406–17.)

**Fig. 9.12.4** Relationship of the Optic Chiasm, Optic Nerves, and Optic Tracts to the Arterial Circle of Willis. The chiasm passes through the circle of Willis and receives its arterial supply from the anterior cerebral and communicating arteries from above and the posterior communicating, posterior cerebral, and basilar arteries from below. (Adapted from Reed H, Drance SM. The essentials of perimetry: static and kinetic. 2nd ed. London: Oxford University Press; 1972.)

Uncommon before age 20, their incidence increases after the fourth decade of life. Autopsy studies reveal that the prevalence of asymptomatic pituitary adenomas may be as high as 20%–27% and that adenomatous hyperplasia may be found in almost every pituitary gland.<sup>15</sup>

Pituitary tumors may be classified as *benign adenomas*, the most frequent pituitary tumor (Fig. 9.12.8), *invasive adenomas*, which grow and invade adjacent skullbase structures and its meningeal coverings, and *pituitary carcinomas*, very rare entities.

Pituitary apoplexy is the sudden enlargement of a pituitary gland as a result from hemorrhage or infarction (most commonly hemorrhagic infarction) of a pituitary adenoma.<sup>16</sup> Pituitary apoplexy is typically associated with acute headache, visual loss, ophthalmoplegia, facial pain, or facial numbness (Fig. 9.12.9).

The normal pituitary gland also may undergo hemorrhagic or non-hemorrhagic infarction, but such episodes generally do not cause visual loss or chiasmal dysfunction and may go unrecognized until hypopituitarism develops. Predisposing factors include pregnancy, estrogen therapy, obstetrical hemorrhage (Sheehan's syndrome), diabetes mellitus, bleeding disorders, long-term anticoagulation, blood dyscrasias, radiation therapy, trauma, angiography, atheromatous emboli, cardiac surgery, coughing, positive pressure ventilation, and vasoactive agents.

The presentation of acute pituitary apoplexy is variable and its course is unpredictable, therefore it should be considered in any patient with abrupt neuro-ophthalmological deterioration associated with headache. Although early investigators suggested pituitary apoplexy occurs primarily

in patients with large macroadenomas, it is now evident that tumors of almost any size may undergo hemorrhagic necrosis.<sup>17,18</sup>

Lymphocytic adenohypophysitis, an immune-mediated diffuse lymphocytic infiltration of the pituitary gland, has been reported to cause chiasmal syndrome from suprasellar extension.<sup>19</sup> This uncommon condition has been reported in women only, and more than one-half of the cases have been found to occur during the perinatal period.

## Meningiomas

In 1929, Cushing and Eisenhardt<sup>20</sup> described the syndrome of bitemporal visual field defects and primary optic atrophy, which occurred with a normal sella turcica as examined by radiography. These findings were most often associated with suprasellar meningiomas, aneurysms, and occasionally with craniopharyngiomas. Suprasellar meningiomas of the sphenoid planum or tuberculum sellae may compress the chiasm from below. Occasionally, the chiasm may be compressed posteriorly by meningiomas that arise from the diaphragma sellae or pituitary infundibulum, laterally by medial sphenoid ridge meningiomas, or above by olfactory groove subfrontal meningiomas (Fig. 9.12.10).

Meningiomas represent 13%–18% of all primary intracranial tumors. The incidence of these tumors increases with age. In one study of 464 patients who had meningiomas, 94% were over 30 years of age.<sup>21</sup> According to other reports, less than 2% of meningiomas occur in patients under 20 years of age, and in this age group, only 2%–4% of primary intracranial

**Fig. 9.12.5 Projections of the Visual Fibers From the Upper and Lower Nasal Quadrants in the Primate.** Upper nasal quadrant retinal fibers remain superior and cross more posteriorly in the chiasm. Lower nasal quadrant retinal fibers remain inferior, cross more anteriorly in the chiasm, loop anteriorly into the terminal portion of the contralateral optic nerve (Wilbrand's knee), and head into the optic tract. (Adapted from Hoyt WF, Luis O. Visual fiber anatomy in the infrageniculate pathway of the primate: uncrossed and crossed retinal quadrant fiber projections studied with Nauta silver stain. Arch Ophthalmol 1962;68:94–106. Figure 8, p. 99.)

**Fig. 9.12.6 Projections of the Visual Fibers From the Lower and Upper Arcades in the Primate.** Arcuate fibers maintain their relative superior or inferior positions as they pass through the chiasm. Upper arcuate fibers enter the medial portion of each optic tract and lower arcuate fibers enter the lateral portion of each optic tract. A vertical line through the foveal center divides the nasal decussating from the temporal nondecussating fibers. (Adapted from Hoyt WF. Anatomic considerations of acute scotomata associated with lesions of the optic nerve and chiasm: a Nauta axon degeneration study in the monkey. Bull Johns Hopkins Hosp 1962;111:57–71.)

**Fig. 9.12.7 Projections of the Visual Fibers From the Papillomacular Bundle in the Primate.** Macular fibers crossing through the chiasm do so in its central and posterior portions. (Adapted from Hoyt WF, Luis O. The primate chiasm: details of visual fiber organization studied by silver impregnation techniques. Arch Ophthalmol 1963;70:69–85. Figure 3, p. 72.)

**Fig. 9.12.8 Pituitary Tumor with Intrasellar Expansion.** Chiasm is easily visible above the tumor, which is separated by a cerebrospinal fluid cistern. The pituitary infundibulum, which arises from the hypothalamus (ventral diencephalon) behind the chiasm, extends downward to the posterior lobe of the pituitary (neurohypophysis).

neoplasms are meningiomas.<sup>22</sup> Meningiomas that occur in adults are known to occur 2–3 times more frequently in women, but this predilection is not found with children. Estrogen and progesterone receptors play a role in the growth of meningiomas.<sup>23–25</sup>

Von Recklinghausen's syndrome (neurofibromatosis-1 [NF-1]), an autosomal dominant inherited condition, is associated with meningiomas, often more than one in a single patient.<sup>26</sup> Multiple meningiomas have an incidence of 1% to 2% in most series. Also, cases of familial meningiomas have been reported. Both familial or multiple meningiomas may or may not be associated with von Recklinghausen's syndrome.

## Craniopharyngiomas

In children and young adults, embryonic vestigial epithelial remnants of Rathke's pouch between the anterior and posterior lobes of the pituitary

**Fig. 9.12.9 Pituitary Apoplexy (T1-Weighted Magnetic Resonance Image).** Pituitary apoplexy in a 32-year-old woman who presented with acute left eye visual loss, headache, and diplopia. Examination showed left side optic neuropathy, bitemporal asymmetric visual field loss, with decreased corneal reflex. Note pituitary macroadenoma necrosis. A large necrotic cyst produces chiasmatic compression and cavernous sinus syndrome with oculomotor paresis.

**Fig. 9.12.11 Cystic Craniopharyngioma Growing Down Toward the Optic Chiasm.** 12-year-old boy presented with progressive visual loss and bitemporal hemianopia.

**Fig. 9.12.12 Glioma of the Optic Nerve, Chiasm, and Hypothalamus in a 13-Year-Old Girl.** Invasion of the hypothalamus or third ventricle dramatically increases the mortality rate from this tumor.

**Fig. 9.12.10 (A) Coronal view.** Tuberculum sellae meningiomas slowly grow posteriorly contacting the optic chiasm. Note optic chiasm is visible as a thin tissue layer draped to the tumor dome. (B) Sagittal view. Infundibular meningiomas may produce chiasmatic compression as the tumor grows rostrally. Note normal pituitary gland inside sella turcica below tumor.

may develop into a benign, frequently cystic tumor called craniopharyngioma (Fig. 9.12.11). Such tumors may occur at any age but have a bimodal incidence, the first peak occurs during the first two decades of life and the second between 50 and 70 years of age. They account for 2%–4% of intracranial neoplasms, 8%–13% of pediatric intracranial neoplasms, 20% of suprasellar masses in adults, and 54% of suprasellar masses in children.<sup>27</sup> Suprasellar, intrasellar, and (rarely) intrachiasmal involvement may be seen. Extension into the third ventricle is common and may lead to hydrocephalus. Rare posterior extension has been documented in association with ventral brainstem and cerebellar compression.<sup>28,29</sup>

## Optic Gliomas

Primary optic pathway gliomas are pilocytic astrocytomas that affect the visual pathways at any location, from the lamina cribrosa, optic nerves, chiasm, or postchiasmatic structures (Fig. 9.12.12).

These tumors often have an indolent clinical course but may be associated with extensive loss of vision from intrinsic involvement by the tumor in the optic pathway.

Unlike with most tumors, there are no reliable histopathological factors predicting outcome in any particular case. Traditional histopathological techniques have not been reliably predictive of clinical course. It is immunogenic characteristics of each tumor (or cell clusters within each tumor) that seems to explain wide differences in the clinical course.<sup>30</sup>

Although patients may be diagnosed at any age, the majority are diagnosed during the first two decades of life. Women and girls are affected as often as men and boys. Many gliomas that infiltrate the chiasm also involve the hypothalamus. Although most are sporadic, up to one-third may be associated with neurofibromatosis type 1.<sup>31–34</sup> Gliomas in adults tend to be more malignant.<sup>35,36</sup>

## Other Causes of Chiasmatic Syndrome

Less common neoplasms that affect the chiasm include chordoma (a type of tumor that arises from the remnants of notochord cells that become sequestered during development), germinoma, endodermal sinus tumor,

leukemia, Hodgkin's and non-Hodgkin's lymphoma, nasopharyngeal carcinoma, and metastatic carcinomas. Non-neoplastic mass lesions that may compress the chiasm include sphenoid sinus mucocoele, arachnoid cyst, Rathke's cleft cyst, epidermoid cyst, fibrous dysplasia, histiocytosis X, dolichoectasia of the internal carotid artery, and aneurysm of the large vessels of the circle of Willis or internal carotid artery. Cavernous hemangiomas, arteriovenous malformations, and venous angiomas may implicate the optic chiasm, bleed into the chiasm, and cause a chiasmal apoplexy. Not infrequently the chiasm also may be compressed from above when obstructive hydrocephalus leads to an enlarged third ventricle.<sup>37</sup> Blindness is often an accompanying symptom of acute hydrocephalus.

Extension of the normal subarachnoid space with prolapse and flattening of the chiasm into an enlargement of the sella turcica is known as empty sella syndrome. As a result of the richly anastomotic blood supply of the chiasm, infarction requires multiple vessel involvement, such as with systemic vasculitis, radiation vasculopathy, or bilateral carotid occlusive disease.<sup>38</sup>

Inflammatory and infectious causes include sarcoidosis, syphilis, other granulomatous diseases, arachnoiditis, abscess, demyelination disease, and lymphoid hypophysitis. Head trauma also may result in a chiasmal syndrome. Postulated mechanisms include tears in the chiasm, contusion necrosis, compression from brain swelling, and delayed hemorrhage. Toxins have been implicated as causes of chiasmal injury. The mechanisms of injury include direct toxicity from chloramphenicol, isoniazid, ethambutol, hexachlorophene, vincristine, and ethchlorvynol, and hemorrhage associated with ethanol-induced coagulopathy. Congenital chiasmal dysplasia may be found in rare cases.

## OCULAR MANIFESTATIONS

### Signs and Symptoms of Chiasmal Lesions

Chiasmal lesions cause loss of vision and visual field defects related to involvement of the chiasm itself, its blood supply, the adjacent optic nerve, or the optic tract. Patients who have chiasmal involvement may be unaware of any deficit, may complain of difficulties related to unrecognized loss of their peripheral field, or may complain of unilateral or bilateral central or peripheral visual loss. If a complete bitemporal hemianopia is present, the affected person may experience loss of depth perception at near, the phenomenon of disappearance of an object as the point of fixation moves forward and leaves the object in an area of blindness behind (Fig. 9.12.13), and "double vision" as a result of overlap or separation of the hemifields associated with a pre-existing phoria, a "hemifield slide" (Fig. 9.12.14).

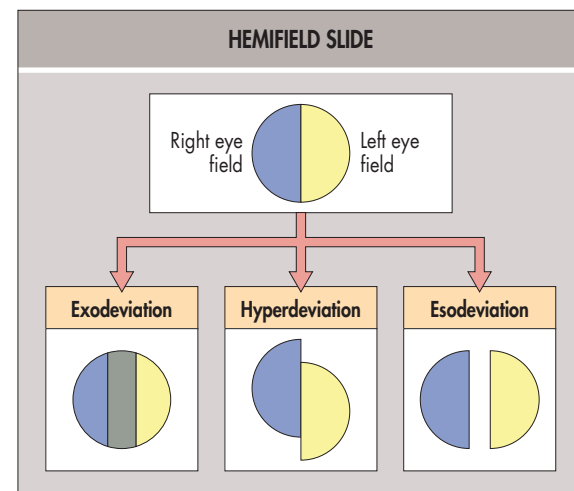

Generally, extrinsic mass lesions become apparent with gradually progressive depression of monocular or binocular vision. However, pituitary adenomas, craniopharyngiomas, or aneurysms may cause acute worsening or fluctuations of vision and can be mistaken for optic neuritis.<sup>39-41</sup> Fluctuation of vision over weeks and months also has been described in some cases of meningiomas, and optic disc pallor may be a late finding with these tumors. Response to treatment with systemic corticosteroids may further mimic the clinical picture of retrobulbar optic neuritis.

The pattern of field loss may suggest the presence of a lesion and further help to localize it (Fig. 9.12.15). Compression of the anterior angle of the chiasm may cause a junctional scotoma, which is a central scotoma, or blindness in one eye plus a contralateral superotemporal defect. Hemianopic arcuate scotomas also may indicate early anterior chiasmal compression. Compression of the body of the chiasm from below, because of a pituitary adenoma for example, generally causes a bitemporal superior quadrantanopia or bitemporal hemianopia. Huber<sup>42</sup> noted that the visual loss associated with sellar meningiomas was more likely to be monocular or markedly asymmetrical if bilateral. Bitemporal inferior quadrantanopia or bitemporal hemianopia occurs with compression of the body of the chiasm from above (e.g., because of a craniopharyngioma). Compression of the posterior chiasm and its decussating nasal fibers may cause bitemporal hemianopic scotomas, but Traquair suggested that this pattern of field loss also may denote a rapidly growing tumor.<sup>43</sup> Less commonly, lateral compression of the margins of the chiasm (e.g., because of dolichoectasia of the carotid siphon or compression of the chiasm into lateral structures) may cause a nasal or binasal hemianopia. Regardless of the pattern, respect for the vertical midline is a feature that helps to differentiate true chiasmal field patterns from other causes.

Because the chiasm is composed of the axons of retinal ganglion cells, chronic involvement (>6 weeks) of the chiasm often leads to nerve fiber layer defects or optic atrophy. When the body of the chiasm is involved, a temporal or "bow-tie" pattern that corresponds to retinal fibers that

**Fig. 9.12.13 Vision With a Complete Bitemporal Hemianopia.** Relative to the point of fixation is a triangular region of blindness behind, a triangular region of binocular vision in front, and regions of monocular vision to each side. As a result, an object may disappear as the point of fixation moves forward and leaves the object in an area of blindness behind. (Adapted from Kirkham TH. The ocular symptomatology of pituitary tumors. *Proc R Soc Med* 1972;65:517-18.)

**Fig. 9.12.14 Phenomenon of "Hemifield Slide."** In patients affected by a complete bitemporal hemianopia, pre-existing phorias may result in separation of the hemifields vertically (hyperdeviation) or horizontally (esodeviation) or in double vision if the intact nasal hemifields overlap (exodeviation). (Adapted from Kirkham TH. The ocular symptomatology of pituitary tumors. *Proc R Soc Med* 1972;65:517-18.)

originate nasal to the fovea may occur (Fig. 9.12.16). However, this appearance often is not apparent, because nondecussating fibers frequently are damaged, as well particularly with compressive lesions. Optic atrophy also may be a late sign of chiasmal compression and is associated with a poorer postoperative visual acuity.

### Signs and Symptoms of Parasellar Lesions

Parasellar involvement manifests with abnormalities of ocular motility, pupillary function, or facial sensation from injury to the third, fourth, ophthalmic, maxillary, and mandibular cranial nerves or the ocular sympathetic nerves in the parasellar region. Injury to these structures within the cavernous sinus may be associated with complaints of diplopia, ptosis, unequal pupil size, accommodative difficulty, facial pain or numbness, or

**Fig. 9.12.15 Localization and Probable Identification of Masses by Pattern of Field Loss.** Junctional scotomas occur with compression of the anterior angle of the chiasm (sphenoid meningioma). Bitemporal hemianopia results from compression of the body of the chiasm from below (e.g., because of pituitary adenoma, sellar meningioma). Compression of the posterior chiasm and its decussating nasal fibers may cause central bitemporal hemianopic scotomas (e.g., because of hydrocephalus, pinealoma, craniopharyngioma).

eye pain. Signs include ocular motor nerve palsies, decreased sensation in the areas innervated by the first and second divisions of the trigeminal nerve, or Horner's syndrome. Multiple cranial nerve involvement is more suggestive of invasive malignant tumors.

Lesions that block the normal cerebrospinal fluid circulation by obstruction of the foramen of Monroe may result in hydrocephalus. Ocular examination may reveal vertical gaze abnormalities, convergence retraction nystagmus, pupillary light-near dissociation, and papilledema.

An unusual form of dissociated nystagmus, termed see-saw nystagmus, occasionally accompanies mass lesions in the chiasmal region and diencephalon. Also, it may be seen transiently immediately after brain-stem stroke, or subsequent to severe head trauma after a delay of weeks to months, or as a variant of congenital nystagmus. See-saw nystagmus manifests as alternating intorsion and elevation of one eye with extorsion and depression of the fellow eye and may result in complaints of oscillopsia. It ceases when the eyes are closed and does not occur in blind patients, which suggests a role for vision in its pathogenesis. A lesion has been postulated that involves the interstitial nucleus of Cajal and its connections or damage to the ocular counter-rolling mechanism mediated by the inferior olivary nucleus.

Chiasmal gliomas in young children have been reported to cause nystagmus, which may be the initial sign of chiasmal or parachiasmal involvement. The nystagmus, which is usually pendular and asymmetrical, may mimic spasmus nutans (even head nodding).

## DIAGNOSIS

### Visual Field Testing

The primary role of the clinician in the diagnosis of chiasmal disorders is to assess visual function accurately, interpret the results correctly, and thus localize the anatomical region that is affected. Visual field tests may provide a strong indication of direct chiasmal involvement, and failure to perform and properly interpret visual field tests is a common cause for delay in the diagnosis of chiasmal disorders. It is important to establish that the

**Fig. 9.12.16 "Bow-Tie" Atrophy.** Chronic compression of the decussating visual fibers of the chiasm leads to atrophy of the corresponding nasal retinal nerve fibers that enter the optic disc nasally and temporally. At the disc, this atrophy appears in a bow-tie pattern.

**Fig. 9.12.17 Pituitary Adenoma With Chiasmal Compression.** Coronal view magnetic resonance scan from a 59-year-old woman who has a bitemporal hemianopia demonstrates a pituitary adenoma that bows the chiasm upward toward the third ventricle. The chiasm is thinned and draped over the mass.

vertical midline forms the border of the field depression and accordingly to rule out nonchiasmal temporal field loss that does not respect the vertical midline. Although a peripheral hemianopic step along the vertical midline is characteristic, early chiasmal compression often lacks a clear vertical step. Most often, temporal paracentral depression occurs because the chiasm has macular projections through most areas. A good strategy to establish a field defect attributable to chiasmal disease is to test either a single central isopter or static threshold sensitivity within the central 15°–20° from fixation and to compare changes in color perception as colored objects pass across the vertical midline through central fixation.

## Neuroimaging

Prompt magnetic resonance imaging (MRI) is indicated for the patient who has symptoms or signs referable to the chiasm or parachiasmal region (see Fig. 9.12.17, Fig. 9.12.9, and Fig. 9.12.10). It is the study of choice for most sellar and parasellar lesions, but high-resolution computed tomography (CT) with fine cuts (1.5–3 mm) of axial and coronal views is also an important imaging aid when planning surgical resection of such lesions. Both modalities provide about equivalent ability to detect lesions in the parachiasmal regions. The advantages of MRI are a better definition of the anatomical relationships to surrounding structures, the absence of artifacts from bone, and the ability to provide axial, coronal, and sagittal

views without special image reconstruction. However, CT provides superior abilities in the detection of tumoral calcifications, of bony erosion and destruction by meningiomas and craniopharyngiomas, and of hyperostosis from meningiomas. Intravenous contrast and enhancement agents (such as paramagnetic gadolinium-pentetic acid for MRI and radiopaque iodine for CT) are used to demonstrate lesions that may not be visualized on noncontrast studies.

## Other Diagnostic Testing

Complete endocrinological evaluation should be done in assessment of lesions that involve the pituitary-hypothalamic axis. Lumbar puncture also may be required if an inflammatory or infectious cause is suspected. Magnetic resonance angiography or cerebral angiography may be indicated when vascular causes or cavernous sinus invasion are suspected, or to further characterize or delineate mass lesions and their blood supply. The current sensitivity of MRI or CT often obviates the need for angiography. Some clinicians still use arteriography to absolutely rule out a suprasellar aneurysm or to define the position of the carotid arteries prior to surgery. However, due to high quality of imaging provided by MRI, transsphenoidal resections of pituitary tumors usually are accomplished safely without prior angiography.<sup>44</sup>

## DIFFERENTIAL DIAGNOSIS

Several conditions may mimic the visual field defects associated with chiasmal syndromes. Retinal conditions (such as nasal sector retinitis pigmentosa), optic disc anomalies (such as tilted optic discs), and papilledema with greatly enlarged blind spots may cause bilateral temporal field loss. Bilateral centrocecal scotomas caused by bilateral optic nerve disease may be difficult to differentiate from posterior chiasmal compression that affects the macular projections unless careful attention is paid to the vertical midline. Visual obstruction from overhanging redundant lid tissue, refractive scotomas, psychogenic visual loss, and test artifacts also may simulate chiasmal field patterns.

## SYSTEMIC ASSOCIATIONS

Headache, usually frontal in location, frequently accompanies pituitary adenomas, pituitary apoplexy, and meningiomas and may be attributable to a stretched diaphragma sellae. Hydrocephalus caused by normal cerebrospinal fluid circulation blockage may lead to headache, gait difficulties, somnolence, and eventually urinary incontinence.

Abnormalities of pituitary endocrine dysfunction cause a variety of symptoms and signs. Many of them are very typical of a specific kind of hormone-producing tumor. Typical features such as thick lips, enlarged eyebrows, increased hand and feet size, large tongue, and metabolic changes including diabetes mellitus and hypertension are common in *acromegaly*. Amenorrhea–galactorrhea syndrome in women and impotence in men are typical features of prolactin-producing tumors, and changes in body habitus, including a full-moon face and centripetal obesity, are associated with Cushing's disease.

Hypothalamic dysfunction also may manifest as urinary frequency as a result of diabetes insipidus, heat or cold intolerance caused by a disturbance of temperature regulation, behavioral changes, lethargy, decreased libido, or disturbance of appetite. In children, delay or arrest in sexual development, precocious puberty, or infantile emaciation may occur.

## PATHOLOGY

### Pituitary Adenomas

Adenomas are by far the most common tumors of the pituitary gland. Tumors usually arise as a discrete nodule from the anterior part of the gland, called adenohypophysis; such microadenomas are soft and vary in color from gray–white to pink or red, depending on the degree of vascularity. As the tumor progressively grows, the normal pituitary gland is pushed away toward the periphery, affecting its normal function. This is the reason many patients with large pituitary adenomas suffer from hypopituitarism (lack or low normal pituitary hormone levels).

Often, the pituitary function (or lack of it) is the most relevant clinical criteria when classifying these kinds of tumors. Functional pituitary tumors are pituitary adenomas that produce hormones. Functional pituitary tumors are therefore classified according to the kind of hormone they produce as:

- Prolactin-(PRL) producing, also known as prolactinomas.
- ACTH-producing, which are adenomas associated with Cushing's disease.
- GH-producing, which are adenomas associated with acromegaly and/or gigantism.
- TSH-producing tumors are considered very rare.

Because they do not produce abnormal hormone levels, nonfunctional adenomas are generally diagnosed due to chiasmatic syndrome or sometimes as an incidental finding during a brain scan for an unrelated reason.

Pituitary adenomas are classified according to size as microadenomas or macroadenomas. Microadenomas are less than 10 mm in their largest diameter, whereas macroadenomas are greater than 10 mm in their largest diameter. In addition, pituitary adenomas may be distinguished anatomically and radiologically as intrapituitary, intrasellar, or extrasellar. Invasive adenomas, which account for approximately 35% of all pituitary neoplasms, may invade the dura mater, cranial bone, cavernous sinus, or sphenoid sinus.<sup>45</sup> Such a finding does matter; according to the World Health Organization, adjacent structure invasion such as cavernous sinus, ethmoid and/or sphenoid sinus, dorsum sellae, or clivus erosion are loosely correlated with tumor recurrence.

Pituitary adenomas can also be classified according to the histological staining affinities of the cell cytoplasm, size, endocrine activity, pathological characteristics, hormone production and contents, ultrastructural features, granularity of the cell cytoplasm, cellular composition, cytogenesis, and growth pattern.<sup>46,47</sup> Recent classifications, however, omit criteria based on tinctorial stains (i.e., acidophilic, basophilic, and chromophobic) because of the poor correlation between staining affinities of the cell cytoplasm and other pathological features of pituitary tumors, such as the type of hormone produced and cellular derivation. A unifying pituitary adenoma classification incorporates the histological, immunocytochemical, and electron microscopic studies of the tumor cells and stresses the importance of hormone production, cellular composition, and cytogenesis. Therefore, pituitary adenomas are named as lactotroph (PRL-producing) adenomas, corticotroph (ACTH-producing) adenomas, somatotroph (GH-producing) adenomas, and thyrotroph (TSH-producing) adenomas. Other tumors may be found to be producers of more than one hormone (plurihormonal adenomas), and up to one-third may be composed of endocrinologically inactive cells (null cell adenomas). In a series of 1000 pituitary tumors surgically resected, Wilson<sup>48</sup> found that just over 77% were secretory (41% prolactin, 19% growth hormone, 17% adrenocorticotropin, and 0.2% thyrotropin). Occasionally, pituitary tumors are associated with other endocrine tumors in the pancreas and parathyroid gland (multiple endocrine neoplasia type 1).

Immunohistochemical analysis is also important as a predictor of future tumor recurrence; elevated mitotic index, a Ki-67 labeling index higher than 3%, and extensive p53 expression are indicators of aggressive behavior.

### Meningiomas

Meningiomas probably derive from cap cells that line the outer surface of the arachnoid (where they serve as the interface between the dura and arachnoid) and within the stroma of the choroid plexus. Histologically, meningiomas are categorized into:

- Syncytial tumors in which the cell borders are indistinct because the cell membranes intertwine extensively.
- Transitional tumors composed of plump polygonal cells and concentrically wrapped spindle cells that form whorls.
- Fibroblastic meningiomas composed of interlacing bundles of elongated cells that simulate fibroblasts.
- Angioblastic meningiomas in which prominent, thin-walled capillaries are found interspersed between the tumor cells.

A characteristic histopathological feature of many meningiomas, especially those in which whorls are prominent, is the presence of psammoma bodies. These structures contain concentric layers of calcium salts, which appear to be deposited within degenerating whorl cells. Whorls and psammoma bodies, characteristic of transitional meningiomas, also may be found (but to a lesser degree) in fibroblastic meningiomas. Malignant meningiomas are rare and usually show cellular pleomorphism and mitoses. However, tumors that appear histologically benign and show rapid growth, local invasion, and metastasis may be determined malignant on the basis of biological behavior.

## Craniopharyngiomas

Craniopharyngiomas may be solid or cystic; the cysts contain an oily fluid, with cholesterol clefts derived from degenerating epithelial cells and keratin. Histologically, the tumor's solid portions may be composed of areas of trabeculae of stratified squamous epithelium supported by a vascularized connective tissue stroma and of areas of peripheral, basal palisading cells that surround layers of stratified squamous epithelial cells, which may form "horny pearls" of keratinized cells. Calcification and deposition of lamellar bone are found frequently. The tumors are surrounded by a capsule of stratified squamous epithelium and often dense gliosis.

## Optic Pathway Gliomas

In children, most gliomas are astrocytomas that consist of pilocytic cells (spindle-shaped cells with hair-like filaments) and stellate cells. Less often, the tumors may comprise evenly distributed oligodendrocytes with dark, round nuclei surrounded by clear halos that may stain with Alcian blue. These tumors have a benign appearance histologically. Eosinophilic hyalinization of apparently degenerated neuroglial cells may form elongated structures called Rosenthal fibers. Formation of microcystic, acellular spaces that contain mucoid material is common. The benign tumors, which are more common in children, are distinct from the aggressive, malignant glioblastoma multiforme that predominates in adults.

## TREATMENT, COURSE, AND OUTCOME

### Pituitary Adenomas

Surgery is the first line of treatment for most symptomatic pituitary adenomas.

Surgery is indicated for all chiasmatic syndrome-producing tumors that will not adequately respond to medical treatment, which is all pituitary tumors, except prolactin-producing and some GH-producing adenomas.

The nonsurgical treatment of pituitary tumors is nonetheless of paramount importance.

The medical treatment of pituitary tumors that are prolactin secreting consists of bromocriptine (an agonist of dopamine D2 receptors) or cabergoline (a dopamine receptor macrolide)<sup>49</sup> and other dopamine agonists that suppress further growth and reduce its size. Normal systemic prolactin levels may be achieved via medical treatment in up to 90% of microadenomas and in more than 70% of macroadenomas.<sup>50</sup> After the institution of bromocriptine therapy, shrinkage of tumor volume and reduction in serum prolactin may occur within days, and maximal shrinkage in tumor size appears to be obtained within 6 weeks. Improvements in visual acuity and field defects may be sustained using bromocriptine therapy in 80%–90% of patients.<sup>51</sup> Unfortunately, about 15% of prolactinomas do not respond adequately to dopamine agonist treatment. Symptomatic pituitary tumor patients that are intolerant, unlikely to respond (cystic prolactinomas), or fail to respond to medical therapy are usually treated by surgical resection, most frequently by the transsphenoidal route.

Prolactinoma treatment success rates depend on the initial tumor size and prolactin levels. In patients with intrasellar microadenomas with prolactin levels under 155 ng/mL, 86% were found to have long-term remissions after transsphenoidal surgical removal.<sup>50</sup> Failure to obtain long-term remission after surgery correlates with higher initial prolactin levels, especially over 200 ng/mL.<sup>52</sup> Overall, recurrence of prolactinomas and pituitary adenomas that secrete growth hormone was 15% at 1 year after transsphenoidal surgery. Pretreatment with bromocriptine does not seem to improve surgical cure rates. Improvement in vision after surgery may be delayed, and final visual outcome is not determined until 10 weeks postoperatively. Improvement does not usually extend beyond 3–4 months.

Some growth hormone-secreting tumors may also respond to bromocriptine, though better results are obtained using octreotide, a somatostatin analog. Response rates of about 80% have been reported.<sup>53</sup>

Symptomatic pituitary tumor patients that are intolerant, unlikely to respond, or fail to respond to medical therapy usually are treated by surgical resection, most frequently by the transsphenoidal route.

## Surgical Treatment

Transsphenoidal approach can be used for 95% of pituitary tumors. Endoscopic techniques have gained much popularity among well-trained otolaryngology–neurosurgery teams. The endoscope provides panoramic magnified views of the sellar anatomy during both the approach and the

resection of tumors itself. The option of using angled endoscopes allows surgeons to inspect for residual tumor, particularly along the cavernous sinus walls and the suprasellar region. During the last decade endoscopic techniques have dramatically improved, and it may become the surgical treatment of choice for many pituitary tumors. Neuronavigation systems are an excellent tool during such surgeries, in particular during recurrent adenomas surgery in which the midline anatomy has been distorted by previous transsphenoidal surgery.

Craniotomy is reserved for very large invasive pituitary adenomas in which vascular control and neural tissue dissection are better served by direct observation and manipulation of tissues.

## Radiation Therapy

Incompletely resected tumors and those unresponsive to hormone therapy are considered for postoperative radiation therapy. Fractions must not exceed 200 cGy daily because of the increased incidence of radionecrosis. Extensive extrasellar extensions usually are treated with surgical decompression followed by irradiation of residual tumor, because a 40% incidence of microscopic dural invasion makes complete resections difficult or impossible to obtain with surgery alone.<sup>54</sup> Patients who have pituitary adenomas that do not immediately threaten vision may be considered as candidates for stereotactic radiosurgery, such as with proton beam, cobalt-60 gamma knife, or linear accelerator therapy.<sup>55</sup> Although endocrine deficit is commonly associated with these modalities, other complications are infrequent and tumor recurrence is rare.

Pituitary apoplexy, which may be life threatening, is treated with high-dose systemic corticosteroids and hormone replacement and may require medical management of either diabetes insipidus or inappropriate antidiuretic hormone secretion. Transsphenoidal decompression of the sella is indicated if rapid visual loss and decrease in level of consciousness occur.

## Meningiomas

The preferred management of meningiomas that involve the intracranial optic nerves and chiasm is surgical removal.<sup>56</sup> Surgical debulking alone, radiation therapy alone, or combination therapy may be performed if vital structures are densely surrounded by tumor. Postoperative radiation therapy of incompletely resected tumors appears to extend the period to tumor recurrence. However, because the tumors grow slowly and this treatment carries the risk of radiation vasculopathy, adjunctive radiation therapy is used only in cases in which progression follows incomplete resection. Another option in some patients includes hormone therapy using the progesterone antagonist mifepristone, which has resulted in reduced tumor size as shown by neuroimaging or improved visual fields in 5 out of 14 patients.<sup>57</sup>

Location of the tumor and duration of visual symptoms are the most important predictors of visual recovery after surgical removal. Meningiomas of the tuberculum sellae and sphenoid wing are generally completely resectable, whereas complete removal of clinoidal meningiomas or diaphragma sellae meningiomas is most unlikely to be complete. Complete gross excision alone does not rule out recurrence. One study showed a 19% 5-year probability of recurrence or progression of parasellar meningiomas despite "complete excision."<sup>58</sup> Visual improvements after tumor resection largely depend on the degree of visual compromise prior to surgery. Long-standing visual symptoms are often associated with large, difficult-to-resect lesions and optic atrophy.

## Craniopharyngiomas

The preferred treatment of craniopharyngiomas remains controversial and is usually customized individually.<sup>59</sup>

Although complete surgical resection of craniopharyngiomas can usually be accomplished through craniotomy, subdiaphragmatic and cystic craniopharyngiomas may be approached transsphenoidally. Intracavitary placement of radioactive or chemotherapeutic agents, including phosphorus-32 colloid,<sup>60</sup> yttrium-90 colloid, bleomycin,<sup>61</sup> or alpha interferon<sup>62</sup> within cystic tumors, has been attempted with some success.<sup>63</sup> Cystic tumors are particularly difficult to manage.

Recurrence is frequent with craniopharyngiomas and usually occurs during the first 2 years after surgery. Due to the tumor's tight attachments to the hypothalamic region, aggressive resections may delay recurrences but lead to greater mortality, as well as visual, endocrine, and neurological morbidity.<sup>64</sup> A review of ambitious attempts at complete surgical removal

showed a 25% operative mortality, a 71% 11-year mortality, and residual tumor in over 75% of those autopsied.<sup>65</sup> Adjunctive radiation therapy improved median survival after extensive subtotal resection from about 3 years to more than 10 years and may achieve remission rates greater than 90%.<sup>66,67</sup> However, adjunctive irradiation is reserved for patients over 5 years of age because of the complications of severe intellectual impairment and profound growth retardation that occur in children.

Visual recovery occurs in only 50% of patients after tumor resection, and the recovery seen within the first month is all that is expected. Lifelong endocrine replacement is expected in most patients after surgery or radiation therapy or both.<sup>68</sup>

## OPTIC GLIOMAS

The treatment of optic chiasmatic–hypothalamic gliomas remains controversial.<sup>69,70</sup> Patients with gliomas that involve the chiasm alone have a mortality of 28% because of the eventual involvement of the hypothalamus or third ventricle.<sup>69</sup> Invasion of the hypothalamus or third ventricle dramatically increases the mortality rate to more than 50% over 15 years (see Fig. 9.12.10).<sup>69</sup> Surgical intervention does not constitute a definitive treatment for these tumors once there is chiasmal or hypothalamic involvement and may be associated with significant visual morbidity and potential mortality. However, studies show benefit from tumor resection in those who have demonstrated rapid expansion of the suprasellar mass with visual deterioration or progressive neurological deficits.<sup>70,71</sup> Shunting procedures are of clear benefit when hydrocephalus is present, and hormone replacement is indicated when endocrine dysfunction occurs. Chemotherapy for progressive chiasmal gliomas has shown promise and in children offers a safer

alternative to radiotherapy.<sup>72</sup> Radiotherapy may be considered in children over the age of 5 years if progression occurs and chemotherapy has been ineffective.

# Lesions of Retrochiasmal Pathways, Higher Cortical Function, and Nonorganic Visual Loss

9.13

Andrew W. Lawton, Michelle Y. Wang

**Definition:** The retrochiasmal pathways are anatomic brain partitions carrying parallel streams of information diverted to appropriate areas of the brain for identification, storage, and retrieval.

## Key Features

- Lesions of numerous areas of the brain produce characteristic interruptions of pathway functions and visual processing.
- Careful analysis of visual fields and function can localize white matter and cortical lesions accurately.
- Because patients with conversion reactions and malingerers may have complaints that mimic those caused by retrochiasmal pathway and cortical injuries, careful evaluation is necessary to avoid unnecessary testing, patient discomfort, and incorrect diagnoses.

## RETROCHIASMAL PATHWAYS AND HIGHER CORTICAL FUNCTION

### OPTIC TRACTS

The optic tracts connect the optic chiasm to the lateral geniculate nuclei. An injury to an optic tract may yield a relative afferent pupillary defect in the contralateral eye. Because of the temporal crescent, the temporal visual field is 50% larger than the nasal field of the contralateral eye. Hence the nasal retina produces axons that constitute approximately 55% of the contralateral optic tract.

The optic tracts do not maintain a strict retinotopic architecture: Tract lesions therefore result in incongruous visual field defects (Fig. 9.13.1). Fibers from corresponding parts of the retinas do not pair in the optic tracts. Larger diameter, faster-conducting axons predominate superficially under the pia. These fibers correspond to the magnocellular layers in the lateral geniculate nuclei. The parvocellular axons dominate the center of the optic tract, with fibers from the opposite eye running in the deepest dorsal regions. The ipsilateral parvocellular fibers sit slightly ventrally. Optic tract axons achieve this orientation by the time they arrive during axonogenesis.

**Fig. 9.13.1 Optic Tract Cross-Section.** Note that the parvocellular fibers run centrally and the magnocellular fibers peripherally.

## LATERAL GENICULATE BODIES

The lateral geniculate bodies are the first sites at which information from corresponding axons arising from the retinal ganglion cell layers pair together. Early embryos do not have this orientation of fibers.<sup>1</sup> The axons rearrange themselves into regular layers. The retina directs the rearrangement process via generation of electrical impulses even before the system is visually active. These impulses arise from ganglion and amacrine cells prior to the appearance of photoreceptors.

Myelinated nerve fibers divide each lateral geniculate body into six neuronal layers.<sup>2</sup> The layers are numbered ventral to dorsal. Axons from the contralateral eye synapse in layers 1, 4, and 6; axons from the ipsilateral eye synapse in layers 2, 3, and 5.

The layers of the lateral geniculate body may be categorized by neuronal size. Large, magnocellular neurons (M cells) predominate in layers 1 and 2; small, parvocellular neurons (P cells) constitute layers 3–6. At this level, visual processing is divided into at least two parallel pathways. The parvocellular pathway involves color perception and visual resolution (high spatial frequency contrast sensitivity), whereas the magnocellular pathway deals with motion detection and lower contrast, lower spatial frequency.

Several authors propose additional parallel pathways.<sup>3</sup> Primate research shows that numerous small neurons (koniocellular or K cells) sit in the interlaminar zones and superficial layers of the lateral geniculate. They receive input from the retina and the region of the superior colliculus. The koniocellular pathways apparently modulate information derived from the other two pathways.

The lateral geniculate nuclei are also organized by retinotopic visual field loci. The macula tends to project to the caudal 75% of the nucleus. These fibers straddle the midline of the nucleus and form a rhombus. The unpaired sections of the visual fields appear to project peripherally within the nucleus. Fibers from the superior retina tend to migrate medially in the lateral geniculate nuclei; those from the lower retina tend to move laterally.

## OPTIC RADIATIONS

Axons arising in the lateral geniculate nuclei form the optic radiations and project to the calcarine cortex. Superior retinal fibers course inferiorly in the radiations and the inferior retinal fibers migrate superiorly (Fig. 9.13.2). Axons corresponding to central vision travel between the two other bundles.<sup>4</sup>

The fibers from the inferior retina travel deep within the parietal lobe relatively close to the internal capsule and to a tract that carries pursuit information from both occipital lobes to the ipsilateral paramedian pontine reticular formation. The superior retinal fibers course ventrally into the temporal lobe in an arc (Meyer's loop) around the temporal horn of the lateral ventricle.<sup>5</sup> These geographical relationships gain considerable importance in localizing a lesion of the visual pathways.

## HIGHER CORTICAL FUNCTION

Information from the optic tracts projects via the radiations to the calcarine cortices of the medial occipital lobes. This visual cortex performs multiple processing functions to prepare information for detailed analysis elsewhere in the brain.

**Fig. 9.13.2 Optic Tract Paths.** Fibers that correspond to the inferior retina course rostrally and laterally into the temporal lobes to form Meyer's loop through the temporal lobe. The superior retinal fibers take a much more direct course through the parietal lobes.

The visual cortex (Brodmann area 17, V1) straddles the calcarine sulci. The neurons of V1 receive information via the myelinated stripe of Gennari. Information from central vision projects to the caudal half of the visual cortex, while peripheral vision projects rostrally.

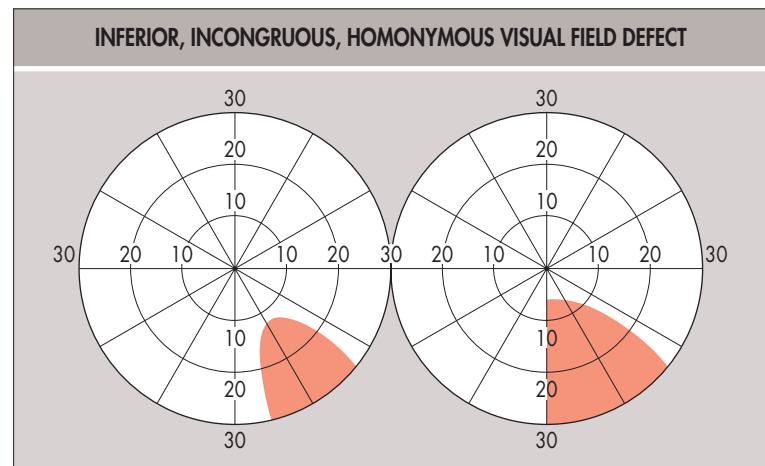

The calcarine cortex plays a smaller role in visual processing than previously theorized. It is a coordination center where information from both hemifields is paired into parallel, vertically oriented, ocular dominance columns.<sup>6</sup> Because the temporal field from the contralateral eye is considerably larger than the nasal field from the ipsilateral eye, each calcarine cortex receives unpaired information from the contralateral eye; this forms the "temporal crescent." This information is processed most anteriorly and aids in the diagnosis and localization of occipital lobe lesions. Connections between the two hemispheres via the corpus callosum allow synchronization and combination of information generated by both fields.<sup>7</sup>

The visual cortex contains four basic types of cells that respond in specific and characteristic ways to retinal stimuli.<sup>8</sup> Circularly symmetrical cells react to small lights independent of movement or orientation. Simple cells respond to a moving light or a dark line or pattern with a specific orientation and direction of motion that projects on the center of their field. Simple cells may turn either "on" or "off" in response to the stimulus. Complex cells respond to linear stimuli almost anywhere in their field but are less specific as to orientation. They also may be "on" or "off" cells. Hypercomplex cells are similar to complex cells but require a linear stimulus of a specific length. The information generated among all these cells is synchronized through the extensive interconnection between visual cortical areas.<sup>9</sup> As a result of this exchange of information, certain stimuli in patterns "pop out" and catch an individual's attention, whereas other details (small gaps in a large pattern especially outside the central 15° or the defect associated with the blind spot) may "fill in" and disappear into the background.<sup>10</sup>

## TOPOGRAPHICAL DIAGNOSIS OF RETROCHIASMAL DISEASE

Lesions involving the visual pathways tend to produce some form of homonymous hemianopia. A total homonymous hemianopia involving the temporal crescent is nonlocalizing. In most cases, however, careful examination of the visual field and associated clinical findings yields clues to the location of a lesion.

Lesions isolated to the optic tracts account for less than 5% of patients with a homonymous hemianopia. Injury to the optic tracts tends to produce exceedingly incongruous field defects. Because the optic tracts include

**Fig. 9.13.3 Inferior, Incongruous, Homonymous Visual Field Defect.** Injuries to the parietal lobe tend to spare central fixation, as is characteristic of temporal lobe lesions.

**Fig. 9.13.4 Visual Field Defect, Temporal Lobe Injury.** Interruption of this segment of the optic radiations yields an incongruous, superior, homonymous visual field defect, more dense above than below—the "pie-in-the-sky" pattern.

fibers of the afferent pupillary pathway, patients with optic tract lesions tend to demonstrate a relative afferent pupillary defect in the contralateral eye and, eventually, optic atrophy on one or both sides. Patients may demonstrate a larger pupil on the side of the hemianopia (Behr's pupil) or pupillary hemiakinesia (Wernicke's pupil).

Lesions to the lateral geniculate nuclei also tend to produce an incongruous homonymous hemianopia. The vascular supply of the lateral geniculate nucleus may include the adjacent thalamus and corticospinal tracts, which provides additional neurological data to localize a lesion clinically. Because pupillary fibers leave the optic tracts rostral to the lateral geniculate nuclei, lesions here do not produce afferent pupillary defects.

Lesions of the deep parietal lobe may involve the superior (superior and peripheral retinal) fibers of the optic radiations. This damage results in a wedge-shaped, inferior, contralateral homonymous hemianopia (Fig. 9.13.3). Because the optic radiation fibers are still orienting themselves for cortical innervation, the hemianopia is incongruous. Because the macular fibers pass between the parietal and temporal fibers, the defect generally spares central vision. The lesion may involve the posterior limb of the internal capsule and produce a contralateral hemiplegia and hemianesthesia. Involvement of the pursuit pathways, headed for the ipsilateral paramedian pontine reticular formation, tends to result in an alteration of optokinetic nystagmus—the patient cannot pursue stimuli moving toward the side of the lesion and does not generate optokinetic nystagmus in that direction.

Damage to the temporal optic radiations interrupts the inferior (inferior and peripheral retinal) fibers of Meyer's loop. The typical visual field defect is an incongruous, wedge-shaped, superior homonymous hemianopia sparing central vision (Fig. 9.13.4). Injury to adjacent structures may yield memory loss, hearing loss, and auditory hallucinations.

Lesions of the calcarine cortex tend to be silent other than for visual field defects. These defects tend to be highly congruous (Fig. 9.13.5).

**Fig. 9.13.5 Visual Field Defect, Inferior Left Calcarine Cortex Lesion.** Note the high congruity and involvement of fixation.

Preservation of the temporal crescent identifies a defect as cortical. Patients may show sparing of central vision (macular sparing); this phenomenon generally results from separate arterial supply between the occipital pole and the rostral calcarine cortex.

Horton and Hoyt<sup>11</sup> mapped the visual cortex in depth by correlating magnetic resonance imaging (MRI) findings and visual dysfunction in patients with occipital lobe lesions. Information from the central 10° of vision involves more than 50% of the caudal striate cortex. Lesions that spare only the temporal crescent are unusual; the central 1° of vision and the entire temporal crescent engage an equivalent cortical volume.

Improved neuroimaging techniques now simplify the evaluation of patients with homonymous hemianopia (see Chapter 9.1). MRI is the method of choice for watershed lesions, small-vessel disease, thrombotic infarction, leukodystrophy, primary or secondary neoplasia, demyelinating white matter disease, shear injuries, or contusion. The MRI should include contrast and noncontrast multiplanar T1- and T2-weighted images. Lesions dominated by blood (acute subarachnoid or intraparenchymal hemorrhage, for example) show poorly on MRI. Noncontrast computed tomography (CT) studies are more productive in these cases. A lumbar puncture may be the only conclusive tool for finding blood.

## CORTICAL REPRESENTATION OF VISION

### INTRODUCTION

The visual association areas of the brain create an image of the world through complex combinations of information from several parallel pathways. The brain separates information by position and category and correlates this information with surrounding objects and associated sounds (Fig. 9.13.6). The brain must maintain a reference library of previously viewed images ready for instantaneous recall that can be applied in unfamiliar contexts. An understanding of the relationship of cortical visual processing pathways enables the recognition of characteristic syndromes by clinical features.

### OBJECT IDENTIFICATION AND MEMORY

Identification of an object requires the ability to retain an image in memory and use this image for future comparison. A patient may be able to identify objects by touch but not by sight.<sup>12</sup> This syndrome comes from damage to the ventrolateral occipital lobes. In contrast, damage to the superior posterior parietal cortex causes difficulty in making the movements needed to manipulate objects despite a preserved ability to describe the objects and their orientation.<sup>13</sup>

One theoretical basis for this separation of function targets visual association areas in the medial occipital lobes.<sup>14</sup> Injury to the right occipital lobe results in failure to identify complex objects (including faces, i.e., prosopagnosia) in general. Apparently, in many animals this area helps to sort out various types of visual stimuli.<sup>15</sup> A lesion in the left occipital lobe yields impairment of recognition of objects with numerous parts, including words.

A second theory concentrates on the connections among lobes of the brain<sup>16</sup> and postulates that primate brains separate visual information into

**Fig. 9.13.6 Distribution of Higher-Order Visual Processing Among Different Cortical Areas.** The magnocellular system (inferior stream) is concerned generally with the location and motion of objects, whereas the parvocellular system (superior stream) is concerned with the fine resolution (acuity), form, and color of objects.

dorsal and ventral streams. The ventral stream originates in the primary visual cortex, projects to the inferotemporal region, and carries information needed to identify objects and their positions in space. The dorsal pathway transmits the information on size, shape, and orientation needed to grasp the object. One stream may be damaged without injuring the other.

The positron emission tomography (PET) scanner provides assistance in resolution of these two theories. Sine-wave gratings yield activity restricted to the striate and extrastriate cortices.<sup>17</sup> Faces stimulate the right parahippocampal region and both fusiform and anterior temporal cortices. Simple objects activate the left occipitotemporal cortex alone. Farah<sup>18</sup> provides an excellent synopsis of the theories of image generation.

Lack of image recognition, however, does not mean an individual cannot see an image clearly.<sup>19</sup> Patients with prosopagnosia fail in selecting two matching faces from a picture set. Invert the faces, however, and the patients fare much better. Inverting the face apparently allows the brain to treat faces as simple objects.

When an image is repeated in a series, necessitating the recurrent identification of the same object, the brain adds another region to the loop. The prefrontal cortex becomes active on PET scan during this task.<sup>20</sup> Although long-term memory for vision is a temporal lobe function, short-term visual memory is a frontal lobe function.

The inability to identify objects visually, however, does not necessarily affect a person's generation of a mental image. Despite a deficit in naming seen objects, patients may copy visual objects, generate accurate pictures from the memory of an object, or draw a picture based upon tactile examination of an object.<sup>21</sup> Ironically, when shown these drawings, patients do not recognize them as their own.

Stimulation of storage areas may produce accurate visual hallucinations that may occur as a release phenomenon resulting from visual loss<sup>22</sup> or abnormal electrical stimulation.<sup>23</sup> Visual hallucinations may result in isolated midbrain injury,<sup>24</sup> although the exact mechanism remains undetermined.

## READING AND DYSLEXIA

Reading represents a very specialized form of visual processing. The unimpaired reader can recognize even sloppy and garbled writing. Multiple regions of the brain are involved, and injury to any of these areas produces recognizable syndromes.

The primary center for reading and writing language appears to be in the dominant angular gyrus in the parietal lobe.<sup>25</sup> Alexia (the inability to read) with agraphia (the inability to write) results from destruction of this area; exceptions to this rule do exist.<sup>26</sup> Alexia without agraphia results from disconnection of the dominant angular gyrus from input from both occipital lobes.<sup>27</sup> This syndrome most commonly results from an infarct in the distribution of the left posterior cerebral artery.

Dyslexia represents a very special form of alexia.<sup>28</sup> By definition, patients with developmental dyslexia have a discrepancy between the acquisition of reading skills and other intellectual abilities, and this disability is not related to environmental conditions, sensory deficits, or acquired neurological disorders.

Investigators have failed to determine a specific site for the origin of developmental dyslexia. One proposal postulates that developmental dyslexia results from deficiencies and depletion in magnocellular pathways<sup>29</sup> based on decreased numbers of magnocellular neurons in the lateral geniculate nuclei from postmortem studies in dyslexic patients. These patients also had decreased responses to low spatial frequency patterns. This theory is not universally accepted, however. It has been challenged,<sup>30</sup> and the definitive answer to an anatomical cause of developmental dyslexia awaits further clinical research.

Phonological dyslexia represents a disorder of association between sounds (phonemes) and letters (graphemes). Some evidence now exists that phonological dyslexia may result from abnormal development of the dominant inferior frontal lobe in areas responsible for control of tongue and lip articulator movements.

## COLOR PERCEPTION

The pathway for the interpretation of color remains separate from those responsible for object identification. PET scanning findings indicate that the lingual and fusiform gyri become stimulated when a normal individual scans for a colored target.<sup>31</sup> Patients who have lesions that cause visual agnosia may maintain the ability to identify the color of objects.<sup>32</sup>

Patients who have acquired central cerebral achromatopsia (inability to identify colors) may have complete loss or miss only one primary color.<sup>33</sup> The isolation of single-color defects links came from research performed in macaque monkeys that showed that an area of prestriate cortex, identified as area V4, contains neurons that respond to specific color stimuli.<sup>34</sup>

Patients with cerebral achromatopsia generally describe objects as “washed out” or “faded.” Patients may still be able to use contrast clues to separate the edge of one intense color from another. If two colors or a color and a shade of gray match pseudoisochromatically, however, patients demonstrate a distinct inability to isolate colored targets. Despite the achromatopsia, other parts of the parvocellular system may remain intact. Patients may have normal visual acuity and contrast sensitivity. Postmortem and radiological studies of these patients reveal bilateral lesions of the inferior occipital cortex.

## INTEGRATION OF VISUAL-AUDITORY SPACE

The brain frequently receives contradictory information from the visual and auditory systems. For example, when an individual watches a movie, an image is seen directly ahead, but sounds are heard from numerous speakers throughout the theater. The brain integrates this information to provide a meaningful and logical integrated experience.

The ability to reconcile auditory and visual cues appears to be learned.<sup>35</sup> This reconciliation is a complicated task, because visual information is received by direct stimulation of an individual retina, whereas auditory localization requires a binaural triangulation of sound. The complexity heightens when the individual or the target moves.

The brain prioritizes visual input.<sup>36</sup> If a sound seems to originate from a seen object, the brain transfers the perception of that sound to the visible source. The process of correlation occurs in the midbrain tectum.

## MOTION DETECTION

Once the brain identifies an object, it must localize that object in relation to the perceiver and the environment and determine the relative rate of

motion of the object to the perceiver. The observer also may be moving, and multiple environmental targets may be moving in different directions. The brain has developed efficient mechanisms to resolve these factors. Injuries may result in the ability to perceive motion in an otherwise blind field or to lose motion detection while the image of the object is preserved.<sup>37</sup>

The primary step in motion detection involves neurons in area V1 of the calcarine cortex supplied by the magnocellular pathway. Motion-sensitive neurons react to movement in a specific direction.<sup>38</sup> The information from these individual neurons then travels to an area (referred to as MT or V5) in the medial temporal lobe. In primates, MT sits in the posterior segment of cortex, bordering the superior temporal sulcus. Almost 100% of the neurons in MT demonstrate directional sensitivity. Evidence suggests that MT represents the first area in which the information related to motion becomes attached to a texture, color, or pattern.<sup>39</sup>

Unfortunately, for simplistic views of motion detection, a moving object in the environment generates multiple bits of information in the MT region. Some bits may appear contradictory. The brain must integrate these signals to form one coherent, three-dimensional representation of relative motion. Approximately 25% of neurons in MT do not react just to linear motion in a single direction but to motion in multiple vectors. These cells may be responsible for motion integration.

## NONORGANIC VISUAL LOSS

Nonorganic (or functional) visual loss represents one of the most difficult challenges faced by ophthalmologists. Nonorganic visual loss cannot be explained by physical examination or ancillary testing and generally falls into one of two categories—conversion reaction or malingering.

Patients with a conversion reaction, previously called hysterical blindness, react to environmental stress. Adolescents seem particularly prone to this kind of response. Because a conversion reaction alleviates tension, patients generally show a flat, relaxed affect despite severe visual complaints. Patients with a conversion reaction appear to honestly believe they are disabled. They tend to be cooperative with testing.

Malingering patients mimic visual loss consciously to obtain an external secondary gain. Their visual complaints appear out of proportion to the underlying original injury. Physicians must take great care with this diagnosis and not equate failure to find a diagnosis with malingering; this diagnosis requires forms of documentation for clinicians as well as judge and jury.

To evaluate patients who have nonorganic visual loss, the examiner starts with the smallest letters possible, in most cases the 20/10 (6/3) line. The physician should pause at each letter and demonstrate concern and confusion that the patient cannot identify these letters. After making the point that the next letters are much larger, the examiner shifts to the 20/15 (6/4.5) line and repeats the process. By the time the patient looks at the 20/20 (6/6) or 20/25 (6/7.5) line, the power of suggestion has set in and the patient generally is convinced the letters are now large enough to read. This technique works well with complaints of either monocular or binocular visual loss.

A 4-diopter prism is an indispensable tool in the evaluation of the visual acuity of patients who have nonorganic monocular visual complaints. The examiner occludes the patient’s “bad” eye, then places the prism over the patient’s “good” eye such that the base is up and the apex splits the pupil. If the prism is positioned in just the right spot, the patient experiences monocular vertical diplopia. The examiner asks the patient if both of the perceived lines appear equally clear; the answer will be “yes.” Once the patient is certain that this test measures the function of the “good” eye, the tester simultaneously uncovers the “bad” eye and slides the prism downward to cover the “good” eye completely. The patient now experiences binocular diplopia but intellectually remains convinced of a monocular phenomenon. At this point, the patient often reads well down the eye chart without hesitation, even when asked to attend to the upper line that corresponds to the “bad” eye.

The red–green eyeglasses provided with the Worth four-dot test may be useful. The examiner asks the patient to put on the glasses and then inserts the red–green filter installed in the vision chart projector. The patient sees the letters on the red half of the eye chart with the eye covered by the red lens and the letters on the green half with the eye covered by the green lens. The patient often progresses well down the eye chart before realizing overachievement has occurred.

The red–green eyeglasses may be used with the Ishihara color plate series as well. If a patient complains of poor vision in one eye, have the patient put on the red–green glasses with the green lens over the “good” eye and the red lens over the “bad” eye. Under normal circumstances, an individual can read the Ishihara numbers through the red lens but

**Fig. 9.13.7 Characteristic "Tunnel" Field of Nonorganic Visual Field Loss.** Paradoxically, the visual field appears to expand as the patient approaches the screen. Such a pattern does not correspond to any known ocular or central nervous system lesion.

not the green lens. If the subject who has nonorganic complaints reads the numbers under the above circumstances, this discrepancy confirms better-than-stated ocular function.

Ophthalmologists often use phoropters and trial frames to confuse patients regarding which eye they are using and obtain a measure of visual acuity. These methods may fail, however, when patients are malingerers. Patients may close an eye surreptitiously and determine which eye they are using. Optokinetic nystagmus only helps ascertain that vision is grossly intact in each eye. A positive test suggests vision is at least 20/400.

Perimetry remains an excellent tool for the evaluation of nonorganic complaints. Both confrontational and tangent screen techniques yield the best information, because they allow variable test distances. Patients who are determined to produce a factitious visual field defect may confound Goldmann and automated perimetry techniques easily, however.

The most common defect discovered during perimetry is a tunnel field. If a visual field is constricted because of organic disease, the absolute size of an isopter for a given test object increases as the distance from the screen increases. Patients who have tunnel fields, however, tend to have field constriction, but they always generate the same absolute size of an isopter on the tangent screen no matter what the test distance (Fig. 9.13.7). The examiner may enhance this tendency by using large, easily discriminated pins to mark the edge of an isopter. Testing at two distances is necessary, however, because several medical conditions (end-stage glaucoma, end-stage papilledema, tapetoretinal degeneration, chiasmal compression, or bilateral occipital lobe infarcts) may produce authentic generalized constriction of the visual field.

The tangent screen may prove useful in another way for the evaluation of patients who have unilateral visual complaints. In one method the visual field is tested for the "good" eye and the location of the blind spot determined. The examiner then tests the "bad" eye and elicits the characteristically small tunnel field inside the blind spot. Finally, the physician evaluates the patient with both eyes open. Patients who have nonorganic complaints frequently lose the blind spot from the "good" eye even though the claimed field for the "bad" eye was smaller than 10°. Occasionally, patients tested in this manner may yield totally inexplicable and impossible visual field changes under binocular conditions. For example, a patient who has a full field in one eye and a tunnel field in the other may report a hemifield loss on the side of the "bad" eye with both eyes open.

Should a patient claim severe bilateral vision loss and be noncompliant on perimetry testing, the examiner must take every opportunity to observe the patient's behavior. If the patient can accurately fix on the examiner's location, a peripheral field much larger than stated is indicated. Patients who have small, bilateral tunnel fields may be able to maneuver easily without bumping into objects. Patients may pick up or take objects held well away to one side, which indicates they can see the objects. Finally, patients who feel no one is watching may perform tasks inconsistent with their level of claimed disability.

Tests for stereoscopic vision may assist the evaluation of patients who have nonorganic complaints. Patients often become intrigued with the challenge of stereoacuity testing and perform at a level well beyond that

claimed under other conditions. Levy and Glick proposed a table estimating the level of visual acuity of the patient's worse eye based on Titmus stereoacuity.<sup>40</sup> The proposed estimate is helpful and has been recently revised.<sup>41</sup>

The examiner may be able to use motility testing to advantage. If a patient complains of a tunnel field, the tester should evaluate saccades initially with two targets very close together. The examiner gradually increases the distance between the two targets and asks the patient to continue to make saccades back and forth. Because a saccade requires voluntary generation to a visible target, patients who have organic visual loss do poorly but those with nonorganic complaints may perform well.

Appropriate evaluation of the pupils constitutes a critical part of the examination of patients who have nonorganic disorders. Asymmetrical visual acuity or field loss between the two eyes must result from intraocular disease or lesions of the optic nerves. Although intraocular disease may not cause an afferent pupillary defect, the examiner usually is able to identify the lesion visually. Unilateral optic nerve disease must produce a relative afferent pupillary defect on the side of the lesion. A patient who complains of markedly poor vision in one eye only, has normal ocular examination findings, and a normal response of the pupils to a light in the "bad" eye is likely to have a nonorganic syndrome.

In certain circumstances, ancillary testing may prove helpful. Electroretinography (ERG) has become a useful tool for nonorganic visual loss evaluation (see Chapter 9.27). Depending on the extent and pattern of vision loss, full field ERG or multifocal ERG may be considered. If a patient generates complaints or findings that suggest a retrochiasmal lesion, imaging studies may be used to identify or eliminate such a lesion as a cause. Should the examiner need further documentation, visual evoked response testing that gives a normal latency and amplitude essentially rules out organic disease as a cause of serious injury to the afferent visual pathway. Malingering patients, however, may prove uncooperative and thwart the efforts of the electrophysiology technician.

Once the examiner has established a patient's complaints as nonorganic, all appropriate findings must be documented carefully in the patient record. The physician must perform all critical tests in the presence of a reliable witness who can corroborate the results in a courtroom.

In most instances, patients who have a conversion reaction respond very favorably to a report of a healthy visual system. The physician must remember that these patients' complaints stem from anxiety; assuaging that anxiety allows the patient to "recover" without stigma. The patient and family must understand that a conversion reaction represents an adaptation to stress; they must work to alleviate the cause of this stress to prevent the development of other somatic complaints.

Malingering patients react poorly to confrontation. Because they seek secondary gain, they immediately challenge demonstrations of their abilities. A good approach is to state that because the physician has not examined the patient previously, an organic lesion may have existed at one time. The examiner can then express concern and relief that the patient's problem has resolved so well and avoid confrontations.

# Disorders of Supranuclear Control of Ocular Motility

9.14

Patrick J.M. Lavin, Sean P. Donahue, Reid A. Longmuir

**Definition:** Loss of voluntary saccades (fast) and pursuit (slow) eye movements from interruption of neural pathways that carry commands from the cerebral cortex to the ocular motor nuclei in the brainstem.

## Key Features

- Disconjugate eye movement disorders and gaze palsies from lesions that involve the prenuclear pathways between the gaze centers and the ocular motor nuclei.
- Abnormal voluntary saccades, pursuit or vergence eye movements.
- Preservation of reflex eye movements (vestibulo-ocular, optokinetic, and Bell's phenomenon).

## Associated Features

- Pyramidal signs (e.g., pseudobulbar palsy, limb weakness, spasticity, hyperreflexia, and extensor plantar responses).
- Extrapyramidal signs (e.g., bradykinesia, dystonia, rigidity, and tremor).
- Evidence of disorders that cause supranuclear gaze palsies (e.g., traumatic or degenerative, demyelinating, neoplastic or vascular diseases).

## INTRODUCTION

With the exception of reflex eye movements (vestibulo-ocular and optokinetic) and the fast phases of nystagmus, cerebral structures determine when and where the eyes move, while the brainstem centers determine how they move.<sup>1</sup>

The final common pathways for eye movements are located in “gaze centers” in the brainstem (Fig. 9.14.1). The paramedian pontine reticular formation (PPRF) contains the premotor substrate for ipsilateral horizontal gaze; and the midbrain reticular formation (MRF) mediates vertical gaze, vergence eye movements, and ocular counter-rolling (Fig. 9.14.2). The PPRF and MRF receive input from a number of “higher” centers, including the cerebral hemispheres, superior colliculus, vestibular nuclei, and cerebellum (see Fig. 9.14.1). They innervate the three ocular motor nuclei. Supranuclear gaze palsies result from interruption of the neural pathways that carry commands for voluntary saccades and pursuit before they reach the brainstem eye movement “generators.”

## ANATOMY OF EYE MOVEMENT

### Anatomy of Supranuclear Eye Movement Control

Eye movements are divided broadly into two types (Box 9.14.1):

- Fast eye movements (saccades) that move the eyes from one target to another.
- Slow eye movements that allow the eyes to follow a target when the target, the head, or both are moving.

Slow eye movements may be conjugate (e.g., pursuit,) or disconjugate (e.g., vergence).<sup>2</sup> The initiation and generation of saccades and pursuit is complex and dealt with in greater detail elsewhere.<sup>1,2</sup> The fast phases of nystagmus (see Chapter 9.18) are also saccades (see Box 9.14.1).

**Fig. 9.14.1 Supranuclear Control of Eye Movements.** The pontine horizontal gaze center (blue) and the vertical gaze center in the midbrain (yellow) receive input from the frontal eye fields to initiate saccades and from the parietal occipital temporal junction to control pursuit. These gaze centers control ocular motility by innervating the ocular motor nerve nuclei (III, IV, and VI).

### Horizontal Eye Movements

The contralateral frontal lobe, particularly the frontal eye field, is responsible for generating horizontal saccades. Each frontal eye field projects to the contralateral PPRF, which innervates the abducens nucleus. Pursuit eye movements are triggered by the ipsilateral posterior parietal lobe (see Fig. 9.14.1), which projects to the PPRF and then to the abducens nucleus. About 60% of the neurons in the abducens nucleus innervate the ipsilateral lateral rectus muscle; the remaining 40% project, via the medial longitudinal fasciculus (MLF), to the contralateral medial rectus subnucleus in the oculomotor nuclear complex (Fig. 9.14.3). Thus, activation of the PPRF or the abducens nucleus generates ipsilateral horizontal gaze; conversely, damage to either of these structures results in an ipsilateral gaze palsy.

### Vertical Eye Movements

The premotor substrate for vertical gaze lies primarily in the MRF. The rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF) contains neurons for both upward and downward saccades. Their axons relay to neurons in the interstitial nucleus of Cajal, which discharge in relation to vertical eye position and play a role in vertical pursuit and eye position. The neurons for upward saccades innervate both ipsilateral

**Fig. 9.14.2 Eye Position During Head Tilt.** The normal ocular counter-rolling reflex maintains relative eye position when the head is tilted. As the head tilts to the left, the right eye excyclotorts and falls while the left eye rises and incyclotorts. The ocular tilt reaction occurs after brainstem injury and is paradoxical. Patients have a head tilt, bilateral torsion, and a sense of a torted vertical meridian all to the same side.

**Fig. 9.14.3 The Vestibulo-Ocular Reflex and Its Contribution to Horizontal Eye Movements.** The semicircular canals respond to rotational acceleration of the head by driving the vestibulo-ocular reflex to maintain the eyes in the same direction in space during head movement. Fibers from the horizontal semicircular canal travel first to the vestibular nuclei and then to each paramedian pontine reticular formation. Excitatory projections that travel to the contralateral sixth cranial nerve nucleus and via the medial longitudinal fasciculus to the ipsilateral medial rectus subnucleus cause gaze to the left. In a similar manner, inhibitory projections are sent to the antagonist ipsilateral lateral rectus and contralateral medial rectus.

### BOX 9.14.1 Types of Eye Movements

#### Saccades or Fast Eye Movements (Velocity Up to 800/Second)

Voluntary (internally triggered)  
Reflexive (externally triggered—by visual or auditory stimuli)  
Spontaneous (searching, rapid eye movements of sleep)  
Fast phases of nystagmus (physiological or pathological)

#### Slow Eye Movements (Velocity Up to 70/Second)

Smooth pursuit  
• Foveal pursuit  
• Full-field pursuit (optokinetic slow phase)  
Vestibular slow phase (includes torsional movements)  
Vergence

#### Other Ocular Oscillations (e.g., Opsoclonus, Flutter)

and contralateral oculomotor and trochlear nerve nuclei (Fig. 9.14.4). The neurons that mediate downward saccades only innervate the oculomotor and trochlear nerve nuclei ipsilaterally (see Fig. 9.14.1). The riMLF and the interstitial nucleus of Cajal also are involved in the generation of ipsilateral torsional eye movements.

The supranuclear pathways for vertical saccades travel from both frontal eye fields to innervate the riMLF on each side in the MRF (see Fig. 9.14.4). Vertical saccades require simultaneous activation of both frontal eye fields.

### Slow Eye Movements

Slow eye movements help maintain fixation on a target to stabilize the image on the fovea when either the subject or object is moving. Four types of slow eye movements occur, namely, pursuit, optokinetic, vestibular, and vergence.

### Pursuit Eye Movements

Pursuit eye movements allow the eyes to track a moving object at velocities up to 70°/second and have a latency of about 125 milliseconds.<sup>2</sup> The generation of pursuit eye movement consists of three essential elements<sup>1,3</sup>:

- A sensory component driven by an image moving across the fovea.
- A motor component generated near the parieto-occipito-temporal junction that projects to the ipsilateral PPRF.
- An attentional-spatial component for concentration on selected targets and orientation in space.

### Vestibular System

Vestibular eye movements maintain foveation when the head moves in any direction or plane, including the horizontal (yaw), vertical-sagittal (pitch), or vertical-coronal (roll) planes. For example, if the subject's head turns 10° to the right, the eyes rotate 10° to the left to maintain fixation of a stationary object (see Fig. 9.14.2). The latency for vestibular responses is about 10 milliseconds.

### Optokinetic System

The optokinetic system complements the vestibulo-ocular system when it becomes inadequate, as with sustained head rotation when the eyes reach the limit in the orbit. In humans the optokinetic system is tested predominantly by foveal fixation and pursuit and, to a lesser extent, by moving visual field stimulation. The latter is tested clinically by rotating an image of the environment around the patient or by turning the patient in a revolving chair so the environment appears to be moving relative to the patient.

### Vergence System

The vergence system enables eyes to move disconjugately in the horizontal plane and allows binocular fixation of an object that moves toward (convergence) or away (divergence) from the subject. The main stimuli for vergence movements are retinal blur (object unfocused) and diplopia (fusional disparity); convergence is associated with accommodation and pupillary miosis (the near triad). The pathways that generate vergence eye movements are not known precisely, but the occipital lobe, midbrain, and cerebellum play significant roles.

**Fig. 9.14.4 Pathways for Vertical Gaze.** Uppgaze pathways originate in the rostral interstitial nucleus of the medial longitudinal fasciculus and project dorsally to innervate the oculomotor and trochlear nerves, traveling through the posterior commissure. Lesions to both axon bundles are necessary to produce upgaze paralysis. Uppgaze paralysis is a feature of the dorsal midbrain syndrome as a result of the lesion's effect on the posterior commissure. Downgaze pathways also originate in the rostral interstitial nucleus of the medial longitudinal fasciculus but probably travel more ventrally. Bilateral lesions also are needed to affect downgaze and usually are located dorsomedial to the red nucleus. *INC*, Interstitial nucleus of Cajal; *IO*, inferior oblique subnucleus; *IR*, inferior rectus subnucleus; *PC*, posterior commissure; *riMLF*, rostral interstitial nucleus of the medial longitudinal fasciculus; *RN*, red nucleus; *SR*, superior rectus subnucleus.

## DIAGNOSTIC TESTING

Techniques used in the examination of the ocular motor system fall into six categories, reviewed in detail by Borchert.<sup>3</sup>

### Saccades

The patient is asked to alternate fixation rapidly between two targets, such as a finger and the examiner's nose. Both horizontal and vertical saccades are tested and observations are made with respect to latency, velocity, and accuracy.

Abnormalities in saccadic accuracy include overshooting (hypermetria) or undershooting (hypometria) the target and indicate cerebellar pathology. Gross abnormalities are clinically obvious, but detection of subtle changes requires quantitative oculography.<sup>2</sup>

### Fixation

The patient looks at a stationary, accommodative target projected in the distance while the examiner checks fixation both monocularly and binocularly. Fixation should be steady without nystagmus or other significant ocular oscillations. Small eye movements such as square wave jerks of less than 1–2° are normal and do not impair vision.

### Pursuit

The patient is asked to fixate a small object, such as a pen, and follow it slowly through the extent of horizontal and vertical versions. The patient's eyes should pursue the target smoothly. If the pursuit system is defective, or the target moves too quickly, the eyes fall behind and make "catch-up saccades" (saccadic or cogwheel pursuit) to refixate the target.

Also, pursuit may be evaluated while testing the patient's ability to suppress the vestibulo-ocular reflex (VOR). Have the patient sit on a rotatable stool and fixate one of his or her own thumbs at arm's length, then rotate the stool so that the patient's head, arm, and thumb move as one. A normal subject can suppress the induced VOR by maintaining fixation on the thumb, even in darkness or with the eyes closed—VOR suppression probably involves the same pathways as smooth pursuit. This technique particularly helps differentiate real from psychogenic visual loss, because blind patients also can suppress the VOR whereas psychogenic patients appear unable to follow a target smoothly.

### Vergence Eye Movements

The patient is instructed to follow a target as it is moved toward (convergence) and then away (divergence) from their face.

### Ocular Alignment

Ocular alignment is covered in more detail in the section on strabismus (see Chapter 11.3). Ocular alignment is determined by simultaneous prism and cover testing (for tropias) and by alternate cover testing (for phorias, and to measure the basic deviation) while in the proper cycloplegic refraction and fixating an accommodative target.

### Differentiating Supranuclear From Nuclear and Infranuclear Lesions

If the patient has a gaze palsy, the physician determines whether the eyes can be moved reflexively in the direction of the "paresis" in two ways:

#### Oculocephalic (Doll's Eyes) Reflex

The oculocephalic (doll's eyes) reflex is performed by tilting the head forward 30° and fixating a distant target. The head is then rotated in the direction opposite the gaze palsy. This maneuver uses direct projections from the vestibular system to the ocular motor nuclei (see Fig. 9.14.3). Gaze palsies caused by lesions of the cerebral cortex typically can be overcome by vestibulo-ocular testing. In prenuclear, nuclear, or infranuclear lesions, the reflex does not overcome the palsy.

#### Vestibulo-Ocular Reflex Testing

The patient's head is tilted back 60° and the external auditory meatus irrigated with either cool or warm water to stimulate the horizontal semicircular canal. In normal subjects and patients with supranuclear gaze palsies, cool water stimulation causes the eyes to deviate slowly toward the irrigated side resulting in nystagmus with the fast (corrective) phase to the opposite side. When warm water is used, the fast phase is toward the stimulated ear. The mnemonic COWS (cool, opposite, warm, same) refers to the direction of the fast phase of the nystagmus. In comatose patients no corrective (fast) phase occurs, so with cold water the eyes deviate tonically toward the irrigated ear. Simultaneous bilateral caloric testing may be used to evaluate vertical eye movements, but this is less reliable than oculocephalic testing.<sup>2</sup>

## DISORDERS OF SUPRANUCLEAR OCULAR MOTILITY

Supranuclear ocular motility disturbances result from interruption of the neural pathways before they reach the eye movement generators. They

**Fig. 9.14.5 The Child Is Spun Around the Examiner to Test the Vestibulo–Ocular Reflex.** The slow tonic phase produces gaze in the direction of the spin; fast phase corrective saccades occur to drive the eyes back. In congenital ocular motor apraxia (congenital saccadic palsy), fast phases are absent and the eyes are driven tonically in the direction of the spin.

may be divided into two groups—disorders of gaze and disorders of vergence eye movements. Gaze palsies affect conjugate eye movements and are characterized by loss of voluntary gaze, in one or more directions, while sparing reflex movements, such as the VOR, optokinetic nystagmus (OKN), and Bell's phenomenon. Disorders of vergence eye movements are disconjugate. Skew deviation and the ocular tilt reaction, which also spare the final common pathway for extraocular eye movements and may also affect reflex eye movements, are referred to in this chapter as prenuclear.<sup>1</sup>

## Congenital Gaze Palsies

Congenital ocular motor apraxia (COMA) or, more correctly, congenital saccadic palsy,<sup>1,2</sup> is more common in boys than in girls; these children find it difficult to initiate saccades and have variable impairment of pursuit. Vertical eye movements remain intact. In early infancy, blindness may be suspected because of the inability to fixate or follow objects. However, after a few months head control is achieved and the patient moves the eyes by thrusting the head in the direction of the target. As the head overshoots the target, the eyes follow the head movement and take up fixation. The head thrusts, usually accompanied with blinks, become less noticeable with time. Confirmation of saccadic palsy is made by spinning the infant around the examiner (Fig. 9.14.5). The eyes move conjugately and slowly in the direction of the spin, but because of the impaired saccades, no corrective horizontal fast phases are seen. COMA may be associated with posterior fossa abnormalities and developmental delay. Ocular motor disorders resembling COMA may be seen in a number of conditions, including Aicardi's syndrome, dysgenesis of the corpus callosum or cerebellum, ataxia telangiectasia, Cockayne's syndrome, Joubert's syndrome, Pelizaeus-Merzbacher's disease, and succinic semialdehyde dehydrogenase deficiency.

Congenital vertical ocular motor apraxia is rare<sup>4</sup> and must be differentiated from metabolic and degenerative disorders, such as neurovisceral lipidosis, and from stable disorders such as birth injury, perinatal hypoxia,<sup>4</sup> and, occasionally, Leber's congenital amaurosis.

Familial horizontal gaze palsy with scoliosis (HGPS) is an autosomal recessive disorder characterized by paralysis of horizontal gaze from birth, progressive scoliosis, impaired optokinetic reflex, and VOR, but intact convergence and vertical eye movements. Some patients may have fine pendular horizontal nystagmus, facial myokymia, facial twitching, hemifacial atrophy, and situs inversus of the optic discs.<sup>2,5</sup>

## Acquired Gaze Palsies

Acquired horizontal supranuclear gaze palsies may occur with stroke, head injury, tumors, seizures and, rarely, with metabolic disease. This subject is reviewed in detail elsewhere.<sup>1</sup> Because these patients have cognitive dysfunction, they can be difficult to examine.

## BOX 9.14.2 Causes of Slow Saccades

Acquired immunodeficiency syndrome dementia complex  
Amyotrophic lateral sclerosis  
Anticonvulsant toxicity (consciousness usually impaired)  
Ataxia telangiectasia  
Hexosaminidase A deficiency  
Huntington's disease  
Internuclear ophthalmoplegia  
Joseph's disease  
Lesions of the paramedian pontine reticular formation  
Lipid storage diseases  
Lytico-bodig disease  
Myasthenia gravis  
Myotonic dystrophy  
Nephropathic cystinosis  
Ocular motor apraxia  
Ocular motor nerve or muscle weakness  
Progressive supranuclear palsy  
Spinocerebellar degeneration (e.g., olivopontocerebellar degeneration)  
Wernicke's encephalopathy  
Whipple's disease  
Wilson's disease

Acute hemisphere stroke can cause a transient gaze deviation.<sup>1</sup> Usually, the eyes are deviated toward the side of the lesion because of paresis of gaze to the hemiplegic side. After about 5 days the intact hemisphere usually takes over and both the gaze paresis and ocular deviation resolve.

Ictal conjugate ocular deviation (seizure activity) occurs as a result of irritative lesions.<sup>6,7</sup> Such lesions “activate” the involved frontal eye field and cause the eyes to deviate away from the damaged hemisphere (adversive gaze deviation). Usually, such ocular deviation is associated with or immediately followed by adversive nystagmoid eye movements. Afterward, because of postictal paralytic conjugate ocular deviation, gaze transiently deviates toward the involved hemisphere as part of Todd's paralysis.

The PPRF may be injured by a variety of lesions including ischemia, hemorrhage, neoplasm, infection, demyelination, and paraneoplastic disorders. A lesion that affects the ipsilateral abducens nucleus or PPRF causes an ipsilateral gaze palsy. A rostral PPRF lesion spares the VOR, whereas a caudal lesion does not. As a result of the proximity of the abducens nucleus and the facial nerve fasciculus, ipsilateral facial weakness typically occurs with caudal PPRF lesions. Rarely, the first-order (central) sympathetic fibers are involved, causing an associated ipsilateral Horner's syndrome.<sup>8</sup>

Wrong-way eyes is the term given to conjugate eye deviation to the “wrong” (hemiplegic) side, that is, away from the lesion and toward the hemiplegic side (contraversive gaze deviation).<sup>9</sup> It may occur with supratentorial lesions, particularly thalamic hemorrhage, but also with ischemic stroke. This can also occur with large perisylvian or lobar hemorrhage or irritative lesions.

Incomplete lesions of the PPRF result in difficulty maintaining eccentric gaze and produce gaze-paretic (gaze-evoked) nystagmus. When the eyes drift back to the primary position, the patient makes corrective saccades back to the eccentric target, which results in gaze-evoked nystagmus.

Bilateral lesions of the PPRF may cause complete loss of voluntary horizontal gaze. Large lesions may extend into the ventral pons, injuring the corticospinal tracts, and render the patient quadriplegic, causing the locked-in syndrome.<sup>10</sup> Such patients appear unconscious, but volitional vertical eye and lid movements are spared, differentiating the locked-in syndrome from coma. Ocular bobbing can occur in this setting (see Chapter 9.18).

Slow saccades occur with pontine disease and a number of disorders listed in Box 9.14.2.<sup>1</sup>

## Disorders of Pursuit

The horizontal pursuit pathways control ipsilateral tracking. The final common motor pathway extends from the parieto-occipito-temporal junction via the dorsolateral pontine nuclei, to the ipsilateral gaze center in the PPRF. With rare exceptions, lesions of the pursuit pathways cause impaired ipsilateral tracking; because the pursuit pathways probably decussate twice,<sup>11</sup> a unilateral midbrain lesion can cause impaired contralateral pursuit.<sup>12</sup> The frontal eye fields, superior colliculi, and cerebellum also contribute to pursuit drive.

Pursuit deficits range from absence of tracking eye movements to saccadic (cogwheel) pursuit. Global impairment of smooth pursuit is a common, nonspecific finding.

Injury to the pursuit pathways also affects the slow phase of OKN, easily demonstrated by rotating an optokinetic drum so that the stripes move toward the affected hemisphere. Because of the proximity of the pursuit pathways to the afferent visual pathways, lesions can cause a contralateral homonymous hemianopia as well.

Balint's syndrome is characterized by apraxia of gaze (inability to look at different parts of the visual field), simultanagnosia (inability to attend simultaneously to different parts of the visual field), and optic ataxia (mislocalization when reaching for, or pointing to, objects). It occurs with bilateral injury to the parieto-occipital region, usually as a result of a prolonged episode of hypotension causing watershed (distal territory) infarction, but also in posterior reversible encephalopathy syndrome (PRES) and in degenerative disorders such as posterior cortical atrophy.<sup>13,14</sup>

## Internuclear Ophthalmoplegia

Injury to the MLF, between the abducens nucleus and the contralateral medial rectus subnucleus of the oculomotor nerve, interrupts transmission of neural impulses to the ipsilateral medial rectus muscle (see Fig. 9.14.3). This impairs adducting saccades of the ipsilateral eye, which become either slow or absent. On attempted lateral gaze, away from the side of the lesion, the abducting eye overshoots the target (dysmetria), giving the appearance of dissociated (disconjugate) nystagmus. If the internuclear ophthalmoplegia (INO) is bilateral, abduction saccades also may be slow because of impaired inhibition of resting tone in the medial rectus muscle. Upward beating and torsional nystagmus are frequently present, particularly if both MLFs are affected. A subtle INO may be demonstrated when the patient makes repetitive horizontal saccades, which disclose slow adduction of the ipsilateral eye. Convergence may be preserved. Other clinical features associated with INO include skew deviation, defective vertical smooth pursuit, impairment of the vertical VOR, as well as impaired ability to suppress or cancel the vertical VOR.

INO also may occur with a variety of disorders that affect the brainstem (vascular, demyelinating, and metastatic) and must be differentiated from the pseudo-INO of myasthenia gravis, paraneoplastic strabismus, or a long-standing exotropia.

The one-and-a-half syndrome occurs with damage to the caudal pons that involves the ipsilateral MLF and either the ipsilateral PPRF or the abducens nucleus. It results in an ipsilateral gaze palsy with an ipsilateral INO (see Fig. 9.14.3). The only intact horizontal movement is abduction of the contralateral eye. If the facial nerve nucleus or fasciculus is involved, oculopalatal myoclonus (a vertical oscillation of the eyes, palate, and other muscles of branchial origin) may develop later.<sup>15</sup> The most common causes of the one-and-a-half syndrome are multiple sclerosis and brainstem stroke, followed by metastatic and primary brainstem tumors. Ocular myasthenia gravis may cause a pseudo-one-and-a-half syndrome.<sup>16</sup>

## Disorders of Vertical Gaze

Isolated midbrain lesions can cause disorders of vertical gaze (see Fig. 9.14.4) and occur with a variety of diseases (Box 9.14.3). Disorders of vertical gaze, particularly downgaze, often are overlooked in patients with brainstem vascular disease, because damage to the nearby reticular activating system impairs consciousness.

Supranuclear upgaze palsies occur with lesions at or near the posterior commissure and with bilateral lesions in the pretectal area (see Fig. 9.14.4). Extrinsic compression of the posterior commissure or pretectal region causes loss of the pupillary light reflex but spares accommodation and convergence (light-near dissociation). Paralysis of upgaze, light-near dissociation of the pupils, impaired convergence, lid retraction, and convergence retraction nystagmus are features of the dorsal midbrain (Parinaud's) syndrome. This condition is most commonly seen in the setting of pineal region tumors, primary brainstem tumors, and midbrain stroke.<sup>17</sup>

Convergence retraction nystagmus is a uniquely localizing sign of injury to the dorsal midbrain region. It is not true nystagmus but a saccadic disorder<sup>2</sup> that is elicited best by rotating an optokinetic drum with the stripes moving downward. When the patient attempts to make corrective upward saccades to refixate, the eyes converge and retract in the orbits because of synchronous co-contraction of the extraocular muscles.

Downgaze palsy occurs with bilateral lesions of the rostral interstitial nucleus of the MLF or its projections (see Fig. 9.14.4). With the exception of occlusion of the posterior thalamosubthalamic branch of the posterior

### BOX 9.14.3 Disorders of the Midbrain That Affect Vertical Gaze

#### Extrinsic Lesions

Pineal region tumors  
Vascular malformations and aneurysms  
Hydrocephalus (failed ventricular shunt)  
Parasitic cysts

#### Intrinsic Lesions

Primary brainstem tumor (glioma, ependymoma)  
Metastatic brainstem tumor  
Third ventricular tumors  
Pituitary adenomas  
Stroke

- Infarction
- Hemorrhage (thalamic, pretectal)

Trauma (surgery, head injury)  
Multiple sclerosis  
Infection (syphilis, encephalitis)  
Lipid storage disease  
Transtentorial herniation  
Kernicterus  
Wernicke's syndrome  
Bassen-Kornzweig syndrome  
Vitamin B12 deficiency  
Jejunal ileal bypass

cerebral artery (Percheron's artery), such discrete lesions are rare; involvement of the midbrain rather than the thalamus is responsible for the paralysis.<sup>18</sup> More commonly, bilateral involvement of the pathways for downgaze and for upgaze occurs as part of diffuse neurological disorders. Rarely, a unilateral lesion of the midbrain tegmentum may result in impaired downward, as well as upward, saccades.<sup>2</sup>

Progressive supranuclear palsy (Steele-Richardson-Olszewski syndrome), a neurodegenerative disorder, occurs in about the sixth decade. It is characterized by vertical supranuclear gaze palsy, particularly for downward gaze, postural instability, and unexplained falls. In addition, nuchal rigidity, Parkinsonism, pseudobulbar palsy, and dementia may be present. Early visual symptoms include blurred vision (making it difficult to see food on a plate and to read), diplopia, burning eyes, and photophobia. As the disease progresses, horizontal eye movements become impaired as well; and eventually a global gaze paresis develops.<sup>2</sup>

Wilson's disease (hepatolenticular degeneration) is associated with a Kayser-Fleischer ring, caused by the accumulation of copper in Descemet's membrane. Eye movement abnormalities are unusual, but slow saccades and supranuclear upgaze palsies may occur.

Kernicterus (neonatal jaundice) can cause upgaze paresis, which usually is supranuclear.<sup>19</sup> Horizontal saccades may be slow in Huntington's disease. Patients find it difficult to initiate saccades and frequently use blinks and head thrusts to facilitate eye movements. Vertical saccades are affected more than horizontal saccades. Fixation instability is prominent.

Tonic upward deviation of gaze (forced upgaze) is rare but may be seen in unconscious patients.<sup>1</sup> It can also be observed in oculogyric crisis, which is often triggered by neuroleptic medications. Rarely, tonic upward gaze deviation may be psychogenic, but it can be overcome by cold caloric stimulation of the semicircular canals.

Benign paroxysmal tonic upward gaze usually starts during the first year of life, lasts about 2 years, and has no known cause. This phenomenon can occur with cystic fibrosis.<sup>20</sup> Tonic upgaze may be seen in normal infants during the first months of life.<sup>21</sup>

Tonic downward deviation of gaze (forced downgaze) is associated with medial thalamic hemorrhage, acute obstructive hydrocephalus, severe metabolic or hypoxic encephalopathy, or massive subarachnoid hemorrhage. When associated with lid retraction, the pupils may be buried below the lower lids (setting sun phenomenon). In this setting, elevated intracranial pressure is a major concern. The eyes may be converged, as if looking at the nose.<sup>22</sup> Preterm infants with intraventricular hemorrhages also may have tonic downward deviation with skew deviation and esotropia.<sup>23</sup> Tonic downward deviation of the eyes may occur as a transient phenomenon in otherwise healthy neonates. It also can be induced in infancy by sudden exposure to bright light.

Skew deviation is a vertical divergence of the ocular axes caused by a "prenuclear" lesion of the vertical vestibulo-ocular pathways in the

brainstem or cerebellum. Skew deviation usually is comitant and frequently associated with cyclotorsion of one or both eyes. When the skew deviation is noncomitant it can mimic a partial third or fourth cranial nerve palsy. Exotropia is often present in combination with skew deviation and internuclear ophthalmoplegia. Skew deviation occurs most commonly with vascular lesions of the pons or lateral medulla (Wallenberg's syndrome). With lesions of the midbrain or upper pons, the contralateral eye is lower (contraversive skew), but with lesions of the lower pons or medulla the ipsilateral eye is lower (ipsiversive skew).<sup>24</sup>

With alternating skew deviation, the hypertropia changes with the direction of gaze. The adducting eye usually is hypotropic, thus mimicking superior oblique overaction. Alternating skew deviation occurs with lesions of either the upper midbrain region involving the interstitial nucleus of Cajal or the cervicomedullary junction or cerebellum. In the latter situation, ataxia and downbeat nystagmus usually are associated.<sup>25</sup> Paroxysmal or periodic alternating skew deviation occurs with midbrain lesions; the hypertropia changes in a regular or irregular manner over periods of seconds to minutes.

Ocular counter-rolling, a normal vestibular reflex, allows people to maintain horizontal orientation of the environment while the head tilts to either side (see Fig. 9.14.2). When the head is tilted to the left, the left eye rises and incyclotorts as the right eye falls and excyclotorts.

The ocular tilt reaction is a special type of skew deviation associated with cyclotorsion of both eyes and paradoxical head tilt all to the same side—that of the lower eye (see Fig. 9.14.2). A tonic (sustained) ocular tilt reaction occurs with lesions of the ipsilateral utricle, vestibular nerve or nuclei, or a lesion in the region of the contralateral interstitial nucleus of Cajal and medial thalamus. A phasic (paroxysmal) ocular tilt reaction occurs with lesions of the ipsilateral interstitial nucleus of Cajal and may respond to baclofen.

Dissociated vertical deviation is an asymmetrical, bilateral phenomenon that occurs with early disruption of fusion (congenital esotropia, infantile cataract). Usually it is manifest during periods of inattention in which the deviating eye elevates, abducts, and excyclotorts. The cause remains unclear, but it is an exception to Hering's law of equal innervation. When manifest, it is best treated by unilateral or bilateral superior rectus recession.<sup>26</sup>

Congenital monocular elevator deficiency, previously known as double elevator palsy, is characterized by congenital limitation of elevation of one eye. Most patients are hypotropic in the primary position but use a chin-up head position to allow fusion. A ptosis or pseudoptosis, in which the upper lid of the affected hypotropic eye appears ptotic because the eye is lower, is almost always present. Monocular elevator deficiency is believed to result from a prenuclear congenital unilateral midbrain lesion because the affected eye usually is elevated by Bell's reflex. Furthermore, because the elevator muscles of the affected eye (inferior oblique and superior rectus) are innervated by their respective subnuclei within the third cranial nerve nucleus but on opposite sides of the midline, a single unilateral lesion must be prenuclear rather than nuclear.

In long-standing monocular elevator deficiency, the inferior rectus muscle may become tight, which may be treated using recession. If no restriction occurs, a full tendon vertical transposition (Knapp procedure) of the horizontal muscles is recommended.<sup>27</sup> Other disorders that may cause inferior rectus restriction, such as thyroid orbitopathy and orbital floor fractures, must be excluded.

Monocular supranuclear (prenuclear) elevator palsy is an acquired limitation of elevation of one eye on attempted upgaze. Patients remain orthotropic in primary position and downgaze is intact. This disorder occurs with unilateral vascular or neoplastic lesions of the midbrain.<sup>1</sup> The affected eye usually is elevated by Bell's reflex or by vestibular stimulation.

## OCULAR MOTILITY DISORDERS AND THE CEREBELLUM

The cerebellum coordinates the different motor and sensory inputs to the ocular motor system and ensures that the eyes move smoothly and accurately. Ocular motility signs indicative of cerebellar disease are listed in Box 9.14.4. The dorsal vermis and fastigial nuclei determine the accuracy of saccades by adjusting their amplitude. Lesions of the dorsal vermis and fastigial nuclei result in saccadic dysmetria. The flocculus is responsible for the stabilization of images on the fovea, particularly after a saccade. Lesions of the flocculus result in gaze-holding deficits, such as gaze-evoked, rebound, or downbeat nystagmus, impaired smooth pursuit, inability to cancel the VOR by the pursuit system, and inability to suppress

### BOX 9.14.4 Ocular Motility Signs Indicative of Cerebellar Disease

Saccadic dysmetria (inaccurate saccadic amplitude; over- or undershooting a visual target)  
Saccadic pursuit  
Unstable fixation (square wave jerks)  
Impaired vestibulo-ocular reflex suppression  
Gaze-evoked nystagmus  
Vertical nystagmus  
Increased vestibulo-ocular reflex gain

nystagmus (and vertigo) by fixation. The nodulus influences vestibular eye movements and vestibulo-optokinetic interaction. Lesions of the nodulus may produce periodic alternating nystagmus.

Posterior fossa tumors may become apparent with strabismus; acute comitant esotropia may be the first sign.<sup>28</sup> Affected children usually are older than those who have infantile or accommodative esotropia and develop nystagmus or other neurological signs.<sup>29</sup> Failure to regain fusion after spectacle, prism, or surgical therapy is common and indicates need for neuroimaging.<sup>28</sup> Congenital or acquired cerebellar defects may be associated with a variety of ocular motility disorders. Patients with COMA may have midline cerebellar defects.<sup>30</sup> Chiari malformations may be associated with downbeat nystagmus, gaze-evoked nystagmus, skew deviation, or divergence-insufficiency esotropia. Familial cerebellar degeneration may be associated with vergence disorders.<sup>31,32</sup>

## OCULAR MOTILITY DISORDERS AND THE VESTIBULAR SYSTEM

The vestibular system stabilizes images on the retina during head movements; the semicircular canals respond to the rotational acceleration of the head by driving the VOR to maintain the direction of gaze in space (on target) during head movements: the otolith (utricle or saccule) respond to linear acceleration and static head tilt responds to gravity. This network is discussed in greater detail elsewhere.<sup>33,34</sup> Disruption of the vertical VOR pathway (peripheral vestibular system, vestibular nuclei, cerebellar inputs, MLF, or cranial nerve subnuclei) causes skew deviation.

## VERGENCE DISORDERS

Convergence paralysis occurs with midbrain lesions and may be associated with other features of the dorsal midbrain syndrome. Lack of effort, however, is the most common cause of poor convergence. Degenerative disorders, such as cerebellar degeneration, Parkinson's disease, and progressive supranuclear palsy, also may be associated with poor convergence. The absence of other midbrain signs and the lack of pupillary constriction on attempted convergence may differentiate psychogenic convergence from organic disease.

Convergence insufficiency is an idiopathic condition that also may in part be related to effort. It is seen in young individuals who complain of diplopia or eye strain in association with near work (asthenopia).<sup>31</sup> This condition is often responsive to "pencil pushups."

Divergence insufficiency is characterized by uncrossed horizontal diplopia at distance in the absence of other neurological symptoms or signs. Patients have intermittent or constant esotropia that is greater at distance than at near. Abduction is full. The origin of divergence insufficiency is unclear, but it may result from a break in fusion later in life or occur in patients with cerebellar degeneration.<sup>32</sup> The condition is treated easily with base-out prisms for the distance correction and rarely requires extraocular muscle surgery.

Divergence paralysis is a controversial entity that is difficult to differentiate from bilateral sixth cranial nerve palsies. Such patients usually have horizontal diplopia at distance with full versions, but abducting saccades are slow. Patients who have bilateral sixth cranial nerve palsies who recover gradually often go through a phase in which the esotropia is comitant and versions are full and thus mimic divergence paralysis.

Spasm of the near reflex is characterized by intermittent episodes of convergence, miosis, and accommodation. Symptoms include double or blurred vision. The patient is esotropic, particularly at distance, and has extreme miosis. Spasm of the near reflex is commonly psychogenic in origin. Patients who have psychogenic spasm of the near reflex often have

associated somatic complaints and behavioral abnormalities, which include blepharoclonus on prolonged lateral gaze. Uncorrected high hyperopia may mimic spasm of the near reflex, but a careful cycloplegic refraction will reveal an accommodative esotropia. The correct management consists of prescribing the full cycloplegic refraction.

Central disruption of fusion, also called posttraumatic fusion deficiency, occurs after moderate midbrain injury and causes intractable diplopia, despite the patient's ability to fuse intermittently and even achieve stereopsis briefly.<sup>33</sup> Prism therapy or surgery is ineffective. Central disruption of fusion also may be associated with brainstem tumors, stroke, neurosurgical procedures, removal of long-standing cataracts, and uncorrected aphakia. It must be differentiated from psychogenic disorders of vergence and bilateral superior oblique palsies; the latter usually cause intolerable cyclodiplopia.

The hemislide phenomenon occurs when patients who have large visual field defects, particularly dense bitemporal hemianopias, develop diplopia. They have difficulty maintaining fusion because they can no longer suppress any latent deviation as a result of loss of overlapping areas of field.

Ocular neuromyotonia is a brief, involuntary, intermittent myotonic contraction of one or more muscles of the extraocular. Although the mechanism is unclear, it is included here because it must be differentiated from other vergence disorders. Ocular neuromyotonia usually results in esotropia of the affected eye with accompanying failure of elevation and depression of the globe and may be provoked by prolonged eccentric gaze. It may be associated with signs of aberrant reinnervation of the third cranial nerve. Usually, the pupil is fixed to both light and near stimuli. Causes include radiation therapy and, less commonly, compressive lesions such as cavernous sinus meningiomas, pituitary adenomas, and, rarely, dolichoectatic vessels. Occasionally no cause is found. It must be differentiated from superior oblique myokymia and the spasms of cyclic oculomotor palsy (see Chapter 9.18). Ocular neuromyotonia responds to carbamazepine and other antiepileptic drugs.

## DEVELOPMENT OF THE OCULAR MOTOR SYSTEM

Maturation of the nervous system continues after birth and is particularly rapid during the first few months of life. At birth the vestibular system is the most developed of the ocular motor subsystems and may be tested by rotating the infant (held at arm's length). The VOR is well developed by the end of the first postnatal week.<sup>34</sup> Smooth pursuit movements occur in neonates but only with large targets (such as a human face) that move at low velocities. The pursuit system does not mature fully until the late teens. The saccadic system also is immature in the neonate. Vertical saccades mature more slowly than horizontal saccades and may not be detected for

the first month after birth. Vergence movements are also slow to mature but are seen after about the first month.

## Transient Ocular Motility Abnormalities in Infancy

Several benign transient ocular motility disorders occur in infancy. Neonatal strabismus occurs in up to one-third of healthy neonates; an esotropia that persists beyond 3 months or an exotropia that persists beyond 4 months postnatally is abnormal.<sup>35</sup> Tonic downward ocular deviation occurs in approximately 2% of otherwise healthy neonates<sup>36,37</sup> and is similar to the "sunset" sign seen in infants with hydrocephalus but resolves spontaneously. Lid retraction, either spontaneous or associated with sudden darkness, may be noted. Tonic upgaze is less common than tonic downgaze but is well described<sup>32,38</sup> and also usually resolves. Skew deviation occurs in healthy infants and usually resolves,<sup>37</sup> but a substantial number of them develop strabismus.

Premature infants, especially those with intraventricular hemorrhages, may develop tonic downward and esotropic ocular deviations similar to that in adults with acquired thalamic lesions. Although the upgaze palsy typically resolves, the esotropia persists and requires surgery.<sup>1</sup>

# Nuclear and Fascicular Disorders of Eye Movement

9.15

Sean P. Donahue, Reid A. Longmuir

**Definition:** Eye movement disorders caused by damage to the ocular motor nerve nuclei (third, fourth, or sixth cranial nerves) or to the ocular motor nerve fascicles within the brainstem.

## Key Features

- Diplopia.
- Incomitant ocular deviation.
- Concomitant localizing neurological signs.

## Associated Features

- Additional cranial nerve palsies.
- Supranuclear disorders of motility.
- Long tract signs.

## INTRODUCTION

Eye movement commands are carried from the cerebral cortex and higher brainstem structures to the ocular motor nerve nuclei. These commands are then sent to the individual extraocular muscles by the third, fourth, and sixth cranial nerves. Eye movement abnormalities resulting from damage to the structures that carry commands to the ocular motor nerve nuclei are considered supranuclear or prenuclear in origin (see Chapter 9.14). Abnormalities resulting from damage to the ocular motor nuclei and their respective cranial nerves are considered infranuclear abnormalities.

An infranuclear ocular motor nerve palsy can be caused by damage anywhere from the nucleus to the extraocular muscle. Nuclear ocular motor palsies occur at the level of the ocular motor nucleus; fascicular nerve palsies are caused by lesions to the nerve fibers that travel from the nucleus and exit the brainstem into the subarachnoid space.

Nuclear and fascicular ocular motor nerve palsies produce characteristic ocular abnormalities, depending on the loss of the function of the innervated extraocular muscle. Acute palsies produce an incomitant strabismus that is greatest in the field of action of the paretic muscle. Palsies of the third nerve are also associated with abnormal pupillary and lid function. Fourth nerve palsies are almost always associated with additional complaints of torsion or with a head tilt or turn.

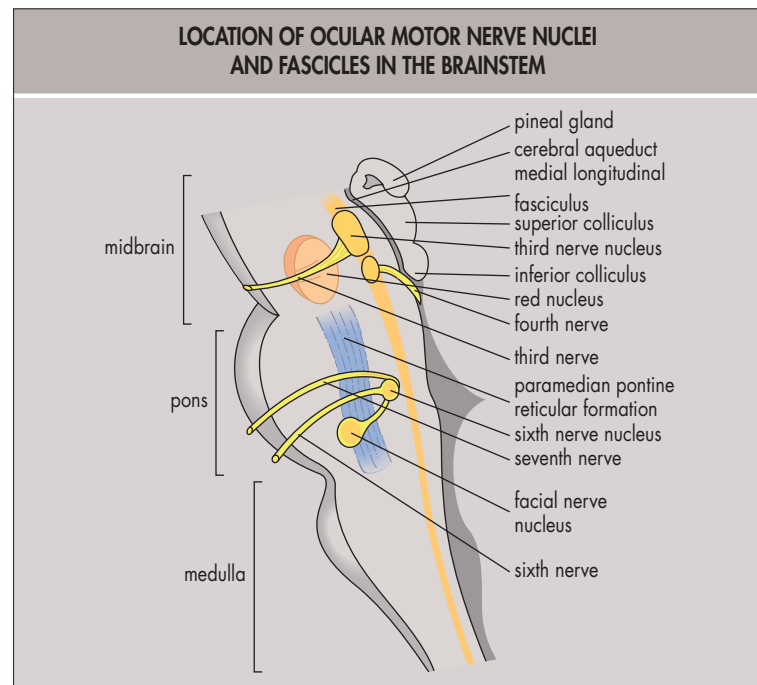

Nuclear and fascicular nerve palsies often are associated with other neurological signs because of the large number of structures located nearby (Fig. 9.15.1). Detailed knowledge of the neuroanatomy of the midbrain and pons enables the clinician to localize these lesions with great accuracy.

## EPIDEMIOLOGY AND PATHOGENESIS

Ocular motor nerve palsies typically become apparent in one of the following four ways<sup>1</sup>:

- Isolated nerve palsies with no other signs or symptoms.
- Isolated nerve palsies with associated symptoms.
- Nerve palsies associated with palsies of other cranial nerves.
- Nerve palsies with neurological signs other than cranioneuropathies.

Each of these four presentations has a different corresponding differential diagnosis. Unfortunately, most of the reports in the literature that

**Fig. 9.15.1 Location of Ocular Motor Nerve Nuclei and Fascicles in the Brainstem.** Note the relationship of the cranial nerve nuclei and fascicles to the medial longitudinal fasciculus, red nucleus, paramedian pontine reticular formation, and facial nerve nucleus and fascicle. The fourth nerve exits dorsally, whereas the third and sixth nerves exit ventrally.

consider the causes of ocular motor nerve palsies<sup>2-5</sup> do not classify the palsies in this manner.

Because nuclear and fascicular disorders are highly localizable, it is better to localize the lesion and then consider the causes based on the patient's age and history (Boxes 9.15.1–9.15.3). Most nuclear and fascicular disorders of eye movement are caused by vascular disease (infarction, hemorrhage from arteriovenous malformation), demyelination, and tumor (metastatic or primary). Infectious, inflammatory, and traumatic causes are less likely. Congenital oculomotor nerve palsy can arise from brainstem disorders in some patients,<sup>6-8</sup> who often have other brain anomalies and brainstem syndromes. Although thyroid disease and myasthenia can mimic isolated cranial nerve palsies, neither is associated with neurological deficits of brainstem function.

## OCULAR MANIFESTATIONS

### Palsies of the Third Cranial Nerve

The oculomotor nerve innervates four extraocular muscles (medial rectus, inferior rectus, superior rectus, and inferior oblique) in addition to the levator palpebrae and the pupillary sphincter.

The degree of involvement of each of these six structures can be quite variable. When the palsy is complete, there is complete ptosis with a dilated pupil that responds to neither light nor near vision. The eye is deviated out and usually, but not always, down. Functioning of the other ocular motor nerves can be assessed in this situation by evaluation of abduction (sixth

### BOX 9.15.1 Etiology of Oculomotor Nerve Palsies of the Nucleus and Fasciculus—Third Nerve Palsies

#### Children

- Congenital
  - With neurological abnormalities
  - With aberrant reinnervation
  - With cyclical oculomotor spasm
- Vascular (arteriovenous malformation)
- Primary tumor
- Metastatic tumor

#### Young Adults

- Demyelinating
- Vascular (hemorrhage or infarction)
- Tumor

#### Older Adults

- Vascular (infarction)
- Tumor

### BOX 9.15.2 Etiology of Oculomotor Nerve Palsies of the Nucleus and Fasciculus—Fourth Nerve Palsies

#### Intrinsic Midbrain Lesions

- Trauma (anterior medullary velum)
- Tumor
  - Medulloblastoma
  - Ependymoma
  - Metastatic
- Demyelination
- Stroke
  - Ischemic
  - Hemorrhagic
- Arteriovenous malformation

#### Extrinsic Midbrain Lesions

- Tumor
  - Pinealoma
  - Metastatic
- Hydrocephalus
- Aqueductal stenosis

### BOX 9.15.3 Etiology of Oculomotor Nerve Palsies of the Nucleus and Fasciculus—Sixth Nerve Palsies

- Vascular disease
  - Hemorrhage
  - Infarction (anteroinferior cerebellar artery; paramedian perforating arteries)
- Demyelinating disease
- Trauma
- Tumor
  - Glioma
  - Astrocytoma
  - Ependymoma
  - Medulloblastoma
  - Metastatic
  - Infiltrative
- Other

cranial nerve) and by observing incyclotorsion on attempted depression in adduction (fourth cranial nerve).

## Third Cranial Nerve Nuclear Lesions

The third nerve nucleus is located in the midbrain near the cerebral aqueduct at the level of the superior colliculus (Fig. 9.15.2). Each extraocular muscle that receives innervation from the third nerve has a corresponding subnucleus (Fig. 9.15.3). A single central nucleus (central caudal nucleus) innervates both levator palpebrae muscles. Distinct, bilateral subnuclei

**Fig. 9.15.2 Anatomy of Midbrain at the Level of the Third Cranial Nerve Nucleus.** The fascicles of the third nerve pass through the red nucleus, substantia nigra, and crus cerebri before they exit into the interpeduncular fossa. The medial lemniscus is nearby. Note the intimate relationship of the oculomotor nerve to the medial longitudinal fasciculus, periaqueductal gray, and the cerebral aqueduct.

**Fig. 9.15.3 Anatomy of the Third Cranial Nerve Nucleus.** The third nerve nucleus consists of a single, central, caudally located nucleus for the levator palpebrae, paired bilateral subnuclei with crossed projections that innervate the superior recti, and paired bilateral subnuclei with uncrossed projections that innervate the medial recti, inferior recti, and inferior oblique muscles. Parasympathetic input to the ciliary body and iris sphincter arises from the Edinger-Westphal nucleus. (From Warwick R. Representation of the extraocular muscles in the oculomotor nuclei of the monkey. *J Comp Neurol* 1953;98:449–503.)

exist for the extraocular muscles. An additional bilateral subnucleus, the Edinger-Westphal nucleus, provides parasympathetic input to the pupillary sphincter.<sup>9</sup>

Projections from the subnuclei to their targets all are uncrossed (each subnucleus innervates the ipsilateral corresponding extraocular muscle), with two exceptions—the single central caudal nucleus sends projections to both levator muscles, and the superior rectus subnucleus projection is crossed. Thus, the right superior rectus subnucleus innervates the left superior rectus muscle, and vice versa.

TABLE 9.15.1 Syndromes of the Third Cranial Nerve Fasciculus

Location	Eponym	Findings
Red nucleus	Benedikt's syndrome	Intention tremor, ataxia, contralateral sensation loss (if medial lemniscus involved)
Crus cerebri	Weber's syndrome	Contralateral hemiparesis

### BOX 9.15.4 Daroff's Rules for Third Cranial Nerve Nucleus Palsies

#### Conditions That Obligate Nucleus Involvement

- Bilateral third nerve palsy without ptosis (bilaterally spared levator function)
- Unilateral third nerve palsy with contralateral superior rectus abnormality and bilateral partial ptosis

#### Conditions That Exclude a Nucleus Lesion

- Unilateral ptosis
- Unilateral internal ophthalmoplegia
- Unilateral external ophthalmoplegia associated with normal contralateral superior rectus function

#### Conditions That Neither Exclude Nor Obligate a Nucleus Lesion

- Bilateral total third nerve palsy
- Bilateral ptosis
- Bilateral internal ophthalmoplegia
- Bilateral medial rectus palsy
- Isolated unilateral single muscle involvement (except levator and superior rectus)

From Daroff RB. Oculomotor manifestation of brainstem and cerebellar dysfunction. In: Smith JL, editor. Neuro-ophthalmology: Symposium of the University of Miami and Bascom-Palmer Eye Institute, vol. 5. Hallandale: Huffman; 1971. p. 104–21.

The evolution of the crossed connections may have occurred to facilitate vestibular innervation. Because the trochlear nerve also undergoes a decussation, each cyclovertical muscle and its corresponding yoked muscle pair have nuclei on the same side of the brain. The right inferior oblique subnucleus and the left superior rectus subnucleus are both located on the right; the left inferior rectus subnucleus and the right superior oblique subnucleus are both located on the left. This allows the direct innervation of a yoked muscle pair from the corresponding semicircular canal without a decussation and is important in the vestibular–ocular counter-rolling reflex.

Although the anatomy of the third nerve nucleus is complex, it allows for precise localization. Daroff<sup>10</sup> has proposed clinical rules that obligate or exclude nuclear involvement (Box 9.15.4). Because the central caudal subnucleus sends projections to both levator muscles, a bilateral third nerve palsy that spares the lid on both sides obligates a rostral nuclear lesion. The crossed projection of the superior rectus subnucleus underlies the observation in that unilateral third nerve lesions with contralateral superior rectus involvement obligate a nuclear lesion, whereas a third nerve palsy with no contralateral superior rectus abnormality cannot be caused by a nuclear lesion.

## Third Cranial Nerve Fascicular Palsies

After leaving the nucleus, the axons of the oculomotor neurons travel through the midbrain. Within the midbrain, they pass near or through two important structures before exiting into the subarachnoid space of the interpeduncular fossa (the red nucleus and the crus cerebri). Lesions that damage the third nerve fascicle within the red nucleus cause a contralateral intention tremor and ataxia. Because the nearby medial lemniscus carries sensory fibers for light touch and proprioception on the contralateral side, these modalities also may be impaired or absent. Lesions of the cerebral peduncle damage corticospinal tract fibers and produce a contralateral hemiparesis. Each of these syndromes has a specific eponym (Table 9.15.1).

Typically, fascicular third nerve palsies affect all functions of the third nerve equally, with the degree of pupil involvement being proportional to the lid and motility defects. However, isolated extraocular muscle pareses can result from fascicular third nerve lesions.<sup>11,12</sup> Divisional oculomotor paresis also can be caused by brainstem lesions.<sup>13</sup> The “isolated,” pupil-sparing third nerve palsy seen in adults with vascular disease may also result from fascicular damage.<sup>14</sup>

Most fascicular third nerve lesions have vascular causes (hemorrhage, infarction). Metastatic or infiltrative disease is less common; demyelinating disease is rare, even in patients with known multiple sclerosis. Because fascicular third nerve palsies are typically ischemic in nature, they may have varying degrees of recovery. Aberrant regeneration, however, does not occur. Patients who have aberrant regeneration after an acquired third nerve palsy must be considered to have a compressive lesion of the third nerve.

## Congenital Third Cranial Nerve Palsies

Congenital oculomotor nerve palsies are rare and are often associated with neurological abnormalities.<sup>6,7,15</sup> Aberrant regeneration is common,<sup>16</sup> which, if present, argues against a nuclear lesion. Loewenfeld and Thompson<sup>16</sup> speculated that perinatal damage to the third nerve causes retrograde degeneration of the oculomotor nucleus, which then is reinnervated haphazardly.

Some patients with congenital oculomotor nerve palsies develop cyclic oculomotor spasm.<sup>16</sup> Typical cases have a slow alternation between a parietic phase, in which the lid droops, the pupil dilates, and the eye turns out, and a spastic phase, in which the lid elevates, the pupil constricts, accommodation occurs, and the eye adducts. These cycles usually persist throughout life. Cyclical oculomotor spasm usually is not associated with acquired lesions of the third nerve.

## Palsies of the Fourth Cranial Nerve

Superior oblique palsy is the most common cause of acquired vertical diplopia and can be either congenital or acquired. Patients who have acquired superior oblique palsies have diplopia that is often worse in downgaze, and they often complain of tilting of their vision. Subjective image separation increases with gaze in the direction opposite the side of the palsy and with head tilt toward the side of the palsy. Motility testing in the acute phase usually demonstrates poor depression in adduction. Orthoptic measurements show hypertropia of the affected eye, with the hypertropia increasing with gaze to the side opposite the palsy and with head tilt toward the side of the palsy. The most common cause of an isolated, acquired fourth nerve palsy is trauma (see Box 9.15.2).<sup>17–19</sup>

Congenital fourth nerve palsies can become apparent at any age. Young children often exhibit abnormal head postures, whereas older individuals typically experience intermittent vertical diplopia. Patients who have congenital fourth nerve palsies have large vertical fusional amplitudes, and old photographs demonstrate a consistent head tilt. Motility often is full in these patients. Orthoptic testing yields results similar to those for acquired fourth nerve palsies.

Although both congenital and acquired fourth nerve palsies usually are isolated, additional neuro-ophthalmological findings occasionally are present that help to localize the lesion and determine whether imaging studies are warranted. Because the fourth nerve fasciculus is quite short, most brainstem-localizing fourth nerve palsies usually involve both the nucleus and the fasciculus.

## Fourth Cranial Nerve Nuclear and Fascicular Lesions

The fourth nerve nucleus is in the midbrain at the level of the inferior colliculus (see Fig. 9.15.1). It lies just caudal to the third nerve nucleus and receives prenucleus input from the vestibular system, the medial longitudinal fasciculus, and the rostral interstitial medial longitudinal fasciculus. The fasciculus of the trochlear nerve travels dorsally to exit the lower midbrain just caudal to the inferior colliculus, near the tentorium. Because the nerve decussates in the anterior medullary velum, fourth nerve nuclear and fascicular palsies are usually associated with superior oblique dysfunction on the contralateral side (Table 9.15.2), but cases of ipsilateral fascicular fourth nerve palsy have been reported in patients with lesions located precisely after the decussation.<sup>20</sup>

Isolated lesions that affect only the trochlear nerve nuclear or fascicular are rare. Most lesions of the area that surrounds the fourth nerve nucleus and fasciculus also affect neighboring structures. Both extrinsic (tumor, hydrocephalus) and intrinsic (tumor, stroke, demyelination, arteriovenous malformation) lesions of the brainstem may damage the trochlear nerves or nucleus and often produce an associated upgaze palsy or features of the dorsal midbrain syndrome (see Box 9.15.2). Lesions that damage the fourth nerve within the dorsolateral midbrain also can damage the first-order

**TABLE 9.15.2 Syndromes of the Fourth Cranial Nerve Nucleus and Fasciculus**

Site of Damage	Laterality of Superior Oblique Palsy	Clinical Manifestations
Pretectal area	Contralateral	Vertical gaze palsy Dorsal midbrain syndrome
Descending sympathetic pathways	Contralateral	Ipsilateral Horner's syndrome
Superior cerebellar peduncle	Contralateral	Ipsilateral dysmetria
Medial longitudinal fasciculus	Contralateral	Ipsilateral internuclear ophthalmoplegia
Brachium of superior colliculus	Contralateral	Contralateral relative afferent pupillary defect Contralateral pupil homonymous hemianopia Normal visual fields
Anterior medullary velum	Bilateral	"V"-pattern esotropia Reversing hypertropias on side gaze >10° excyclotorsion

(descending) sympathetic fibers to produce a contralateral fourth nerve palsy with an ipsilateral Horner's syndrome.<sup>21</sup> Damage to both trochlear nerve fascicles at their decussation within the anterior medullary velum produces a bilateral superior oblique palsy, which is often asymmetrical. These patients can have a V-pattern esotropia, reversing hypertropias on gaze and tilt, and greater than 10° of subjective excyclotorsion.<sup>22</sup> These patients may also show features of dorsal midbrain syndrome.<sup>23</sup>

An interesting fascicular syndrome of the fourth nerve involves the brachium of the superior colliculus.<sup>24</sup> Pupillomotor fibers pass through this structure as they travel from the optic tract to the pretectum. These fibers subserve the pupillary light reflex from the contralateral visual field. Because the retinogeniculate pathway has already separated from the pupillary pathways, conscious light detection is not affected, but the pupillary light reflex is. Patients who suffer lesions in this area have normal visual fields but a small (0.6–0.9 log unit) relative afferent pupillary defect in the eye contralateral to the lesion, consistent with an optic tract lesion. The fourth nerve palsy is also on the contralateral side (the fascicle is damaged before the decussation).

## Palsies of the Sixth Cranial Nerve

The sixth nerve innervates the ipsilateral lateral rectus muscle and produces abduction. Damage to the sixth nerve produces an esotropia that is worse in the field of action of the involved sixth nerve and greater at distance than at near. Most patients are able to fuse with a face turn toward the side of the palsy (gaze away from the palsy). The pupil is not affected. Patients who have long-standing sixth nerve palsies can develop tightening and contracture of the medial rectus, which causes a restrictive strabismus with positive forced ductions. Occasionally, patients who have long-standing sixth nerve palsies may have associated vertical diplopia and hypertropia.<sup>25</sup> Nuclear and fascicular lesions of the sixth nerve typically have characteristic findings.

## Sixth Cranial Nerve Nuclear Palsies

The sixth nerve nucleus is in the pons, just ventral to the floor of the fourth ventricle. The fascicle of the facial nerve wraps around the sixth nerve nucleus (Fig. 9.15.4). The sixth nerve nucleus contains bodies of two types of neurons—most project directly to the lateral rectus muscle, but about 40% of the cells in the abducens nucleus are interneurons, which project, via the medial longitudinal fasciculus, to the contralateral medial rectus subnucleus and cause adduction of the contralateral eye. Thus, the sixth nerve nucleus, like the paramedian pontine reticular formation, is a gaze center. Damage to the sixth nerve nucleus or to the caudal paramedian pontine reticular formation produces an ipsilateral gaze palsy that cannot be overcome by vestibular testing. Because all nuclear sixth nerve palsies produce a gaze palsy, an abduction deficit not associated with contralateral adduction weakness cannot arise from damage to the nucleus.

The location of the sixth nerve nucleus within the brainstem produces several possible associated deficits when a nuclear sixth nerve palsy is present (Box 9.15.5). The intimate relationship between the facial nerve

**ANATOMY OF THE SIXTH NERVE NUCLEUS IN THE PONS**

**Fig. 9.15.4 Anatomy of Sixth Cranial Nerve Nucleus in the Pons.** The abducens nucleus is surrounded by the facial nerve fasciculus after it originates from its nucleus and is associated intimately with the medial longitudinal fasciculus. Abducens fascicles traverse the paramedian pontine reticular formation and the corticospinal tract before leaving the lower ventral pons. The vestibular nuclei and spinal nucleus and tract of the trigeminal nerve are nearby in the lateral pons.

**Fig. 9.15.5** T2-weighted magnetic resonance imaging scan of a 33-year-old woman who has a left abduction deficit, gaze paretic nystagmus on left gaze, and left facial weakness. The cause of this nuclear sixth nerve lesion (long arrow) most likely was demyelinating disease. A second lesion can be seen in the right cerebellum (arrowhead).

## BOX 9.15.5 Sixth Cranial Nerve Syndromes of the Nucleus and Fasciculus

### Sixth Nerve Nucleus Palsies

- One-and-a-half syndrome (obligate)
- Foville's syndrome
- Gaze palsy
- Peripheral facial palsy (likely)

### Fascicular Sixth Nerve Palsies

- With contralateral hemiplegia (Raymond's syndrome)
- Facial weakness (Millard–Gubler syndrome)

fasciculus and the sixth nerve nucleus produces an ipsilateral peripheral facial nerve palsy in nearly all cases of abducens nuclear injury (Fig. 9.15.5).

When damage from either the sixth nerve nucleus or the paramedian pontine reticular formation also involves the ipsilateral medial longitudinal fasciculus, a characteristic motility pattern is produced, consisting of an ipsilateral gaze palsy with an ipsilateral internuclear ophthalmoplegia. The ipsilateral eye cannot adduct or abduct, and the contralateral eye can only abduct. This syndrome is called *one-and-a-half syndrome*.<sup>26</sup>

Most nuclear abducens palsies are caused by infarction (anteroinferior cerebellar or paramedian perforating arteries), demyelination, or

compression (intrinsic pontine tumors). Infiltrative disease, hemorrhage, and trauma are less likely causative factors (see [Box 9.15.3](#)).

## Sixth Cranial Nerve Fascicular Palsies

Nearly all fascicular lesions of the abducens nerve are associated with distinctive neurological findings that result from damage to the surrounding neurological structures of the pons (see [Box 9.15.5](#)). These eponymous syndromes and their findings are listed in [Box 9.15.5](#). Because most lesions can affect both the dorsal and the ventral pons, a clinical overlap exists between these syndromes.

Common causes of fascicular lesions include infarction, compression (cerebellar pontine angle tumor or glioma), infiltration, and demyelination and vary with the age of the patient.<sup>1,3,27</sup> Hemorrhage, trauma, and infection are less likely (see [Box 9.15.3](#)).

Classic teaching in pediatric ophthalmology held that isolated sixth nerve palsies in childhood should be considered the result of a pontine glioma until proven otherwise.<sup>27</sup> However, the definition of isolated palsy used in the study by Robertson et al. meant that no other cranial nerve palsies existed and not that the remainder of the neurological examination was normal. Most children with pontine gliomas develop other neurological findings within a few weeks, and therefore a careful neuro-ophthalmological examination with close follow-up probably is all that is necessary in children (under age 14 years) who have truly isolated idiopathic sixth nerve palsies.

## DIAGNOSIS

Complete third nerve palsy is recognized by the simultaneous presence of ptosis, mydriasis, and paralysis of adduction, elevation, and depression. The eye is turned “down and out” because of the unopposed actions of the lateral rectus and superior oblique muscles. Fourth nerve palsy is diagnosed in the presence of hypertropia, which is worse in opposite gaze and in same-sided head tilt (Parks-Bielschowsky three-step test), along with excyclotorsion on the affected side. Sixth nerve palsy is seen as an abduction deficit, with decreased abducting saccadic velocity. Diagnosis of isolated cranial nerve palsy is covered in greater detail in Chapter 9.16.

## Palsies of the Third Cranial Nerve

Attention should be paid to vertical gaze abnormalities because the centers for vertical gaze are in close proximity to the oculomotor nucleus and also are often damaged. Magnetic resonance imaging (MRI) is the best method by which to assess the integrity of midbrain structures in patients who have acute palsies. The neuroradiologist should be informed of the clinical localization so that attention can be directed to this area.

## Palsies of the Fourth Cranial Nerve

Patients who have acquired fourth nerve palsies with localizing signs should undergo imaging studies, with attention paid to the areas suggested by the clinical findings. Patients who have no risk factors for vascular disease, no history of trauma, and no findings suggestive of a decompensating congenital fourth nerve palsy should undergo imaging studies.

## Palsies of the Sixth Cranial Nerve

Patients who have brainstem findings need further assessment with MRI and appropriate management.

## TREATMENT, COURSE, AND OUTCOME

### Palsies of the Third Cranial Nerve

In many patients with microvascular oculomotor nerve palsies, there is improvement eventually. Ptosis is advantageous because it prevents

diplopia. Strabismus correction and lid surgery are needed to restore binocularity in patients whose condition does not improve spontaneously; the chapter author waits for a period of 6 months for stable measurements to occur before suggesting surgical alignment.

## Palsies of the Fourth Cranial Nerve

Palsies of the fourth nerve that result from vascular disease or trauma often resolve spontaneously over 3–6 months. During this time, Fresnel prisms can be placed over spectacles to allow fusion. However, this often is fraught with difficulty because the deviation is usually quite incomitant and torsion cannot be corrected. Patients who have fourth nerve palsies that arise from compressive lesions often do not experience improvement in their condition and require surgery.

Surgical options for the treatment of superior oblique palsy are complex and are beyond the scope of this chapter. Congenital superior oblique palsies often are associated with abnormalities of the insertion of the superior oblique tendon.

## Palsies of the Sixth Cranial Nerve

Nearly all patients who have sixth nerve palsies experience diplopia. During the acute phase, this condition is best managed by patching the paretic eye or by frosting a spectacle lens. Prisms usually are not well tolerated because of the magnitude and incomitance of the deviation. Botulinum toxin injection probably does not decrease the need for later surgical intervention of unilateral sixth nerve palsy.<sup>28,29</sup>

Surgical intervention for sixth nerve palsy is indicated when the deviation has been stable for a minimum of 6 months. The choice of surgical procedure for chronic sixth nerve palsies depends on the recovery of function of the lateral rectus muscle, which can be assessed by determining the saccadic velocity. Patients who experience good return of function usually do quite well with an ipsilateral recess–resect procedure, whereas those having poor lateral rectus function need transposition. Patients who have little or no lateral rectus function need muscle transposition surgery.

# Paresis of Isolated and Multiple Cranial Nerves and Painful Ophthalmoplegia

9.16

Adam DeBusk, Mark L. Moster

**Definition:** Dysfunction of one or more of the three cranial nerves that move the eyes.

## Key Features

- Diplopia.
- Dysconjugate gaze.

## Associated Features

- Ptosis.
- Pupillary abnormalities.
- Pain.
- Proptosis.
- Chemosis.
- Arterialization of conjunctival vessels.

## INTRODUCTION

One of the common clinical presentations in neuro-ophthalmology involves dysfunction of the ocular motor nerves—third (oculomotor nerve), fourth (trochlear nerve), and sixth (abducens nerve) cranial nerves. In this chapter, the anatomy of the peripheral course of the ocular motor nerves is reviewed, and various clinical syndromes are discussed. The syndromes include isolated involvement of each nerve, involvement of multiple cranial nerves simultaneously, involvement of the third, fourth, and sixth cranial nerves with other neurological or orbital symptoms and signs, and involvement of these cranial nerves in severe pain. An approach to the differential diagnosis of patients who seek treatment for involvement of the ocular motor nerves and guidelines for evaluation and treatment are also given.

## ANATOMY

The clinical localization and subsequent differential diagnosis of cranial neuropathies requires knowledge of the anatomy of the third, fourth, and sixth cranial nerves. The anatomy within the brainstem is covered in Chapter 9.15; here, the relevant anatomy of the motor nerves from the brainstem exit to the eye is given (Fig. 9.16.1).

The third cranial nerve exits the midbrain ventrally to enter the subarachnoid space. It continues forward and laterally, passes between the posterior cerebral artery and superior cerebellar artery, and then runs alongside the posterior communicating artery. The nerve pierces the dura to enter the cavernous sinus, where it runs along the lateral wall, superior to the fourth cranial nerve. It enters the orbit via the superior orbital fissure. In the anterior cavernous sinus, it divides into the superior and inferior divisions. The superior division ascends lateral to the optic nerve to supply the superior rectus and levator palpebrae superioris muscles. The inferior division divides into branches that supply the inferior rectus, inferior oblique, and medial rectus muscles and the pupillary sphincter. Parasympathetic preganglionic fibers travel along the branch to the inferior oblique and terminate in the ciliary ganglion near the apex of the extraocular muscle cone lateral to the optic nerve. The postganglionic

fibers from the ciliary ganglion travel in the short ciliary nerves, along with the sympathetic fibers, to enter the globe at the posterior aspect near the optic nerve. They terminate in the ciliary body and iris, and control pupillary constriction and accommodation via the ciliary muscles.

The fourth cranial nerve exits the midbrain dorsally and crosses to the opposite side, within the anterior medullary velum, just below the inferior colliculi. The nerve courses forward within the subarachnoid space around the cerebral peduncle and runs between the posterior cerebral and superior cerebellar arteries, along with the third nerve. The fourth cranial nerve pierces the dura at the angle between the free and attached borders of the tentorium cerebelli to enter the cavernous sinus. It runs within the lateral wall of the cavernous sinus, just below the third cranial nerve and above the first division of the fifth cranial nerve (trigeminal nerve). It enters the orbit via the superior orbital fissure, but runs outside the annulus of Zinn and diagonally across the levator palpebrae superioris and superior rectus muscle to reach the superior oblique muscle. It supplies the superior oblique muscle, the main action of which is incyclotorsion. Secondary actions are depression of the eye in the adducted position and abduction of the eye.

The abducens nerve exits the brainstem at the junction of the pons and pyramid of the medulla, and ascends through the subarachnoid space along the surface of the clivus. It runs forward over the petrous apex of the temporal bone, beneath the petroclinoid ligament, and through Dorello's canal to enter the cavernous sinus. In the cavernous sinus, it runs lateral to the internal carotid artery, but medial to the third and fourth cranial nerves and the first and second divisions of the fifth cranial nerve, which run in the lateral wall. It enters the superior orbital fissure, within the annulus of Zinn to innervate the lateral rectus muscle.

## OCULAR MANIFESTATIONS

### General Symptoms

The usual symptom associated with dysfunction of the ocular motor nerves is binocular diplopia. Diplopia occurs when an object projects onto retinal points that do not correspond in both eyes. The diplopia is worst in the direction of action of the weak muscle(s), but it may not occur with poor visual acuity, ptosis, or a history of congenital strabismus.

On examination, a patient who has binocular diplopia demonstrates an ocular deviation. Numerous examination techniques are available to measure ocular deviations, including prism lenses with the cover–uncover or alternate cover technique, the red glass test, the Maddox rod, and the Hess or Lancaster screen. Proficiency in at least one of these techniques (see Chapter 11.3) is necessary to adequately assess patients with diplopia.

An ocular deviation that is variably present when fusion is broken is termed *phoria*, whereas an intermittently or constantly manifest deviation under binocular conditions is referred to as *tropia*. When a measured deviation is similar in all gaze directions, it is a *comitant* deviation; when it varies by direction it is *incomitant*. Congenital strabismus most often presents with a comitant deviation.

Acquired cranial neuropathies appear with a ductional deficit on examination that corresponds to weakness in the appropriate muscle(s) innervated by the cranial nerve(s) involved. In a more subtle deficit, ductions may appear full, but an incomitant deviation greatest in the direction of action of the paretic muscle is seen. When a cranial neuropathy is chronic, spread of comitance may occur, and the deviation mimics that of congenital strabismus.

## THIRD, FOURTH, AND SIXTH CRANIAL NERVES, LATERAL VIEW

**Fig. 9.16.1** Lateral view of third, fourth, and sixth cranial nerves from the brainstem nuclei to the orbit. The third nerve exits the midbrain anteriorly, crosses near the junction of the internal carotid and posterior communicating artery in the subarachnoid space, and enters the cavernous sinus, where it runs in the lateral wall. The fourth nerve exits the midbrain posteriorly and crosses to the opposite side, to move forward in the subarachnoid space and into the cavernous sinus. The sixth nerve exits the pons anteriorly, ascends along the clivus bone, crosses the petrous apex, and descends below the petroclinoid ligament to enter the cavernous sinus, where it runs between the lateral wall and the carotid artery.

## Isolated Cranial Neuropathies

In this section, the assessment of patients affected by isolated involvement of the third, fourth, or sixth cranial nerve, with no other neurological or ophthalmologic signs, is discussed.

### Isolated Sixth Cranial Nerve Palsy

An isolated sixth nerve palsy appears with a unilateral abduction deficit of variable degree, from a complete inability to abduct past the midline to a mild incomitant esodeviation greatest on lateral gaze. Abduction saccades in the affected eye are slow. The history consists of binocular uncrossed diplopia, worse in the direction of the lesion and worse at distance than at near. [Fig. 9.16.2](#) demonstrates the deviation seen when using a Maddox rod in a patient who has a right sixth nerve palsy.

Congenital sixth nerve palsy is rare and may be related to birth trauma. The deficit resolves in the first month of life.<sup>1,2</sup> Other congenital abnormalities of the sixth nerve, such as Mobius' syndrome and Duane's retraction syndrome, show additional findings and are discussed in the section on [differential diagnosis](#).

Traumatic sixth nerve injury is often associated with fractures of the petrous bone or clivus. Other clinical findings include mastoid ecchymosis (Battle's sign) and cerebrospinal fluid (CSF) otorrhea. Head trauma with subsequent elevated intracranial pressure may cause unilateral or bilateral sixth nerve palsy. Causes of chronic sixth nerve palsy include those of acute sixth nerve palsy but more often are from a compressive lesion.<sup>3-5</sup>

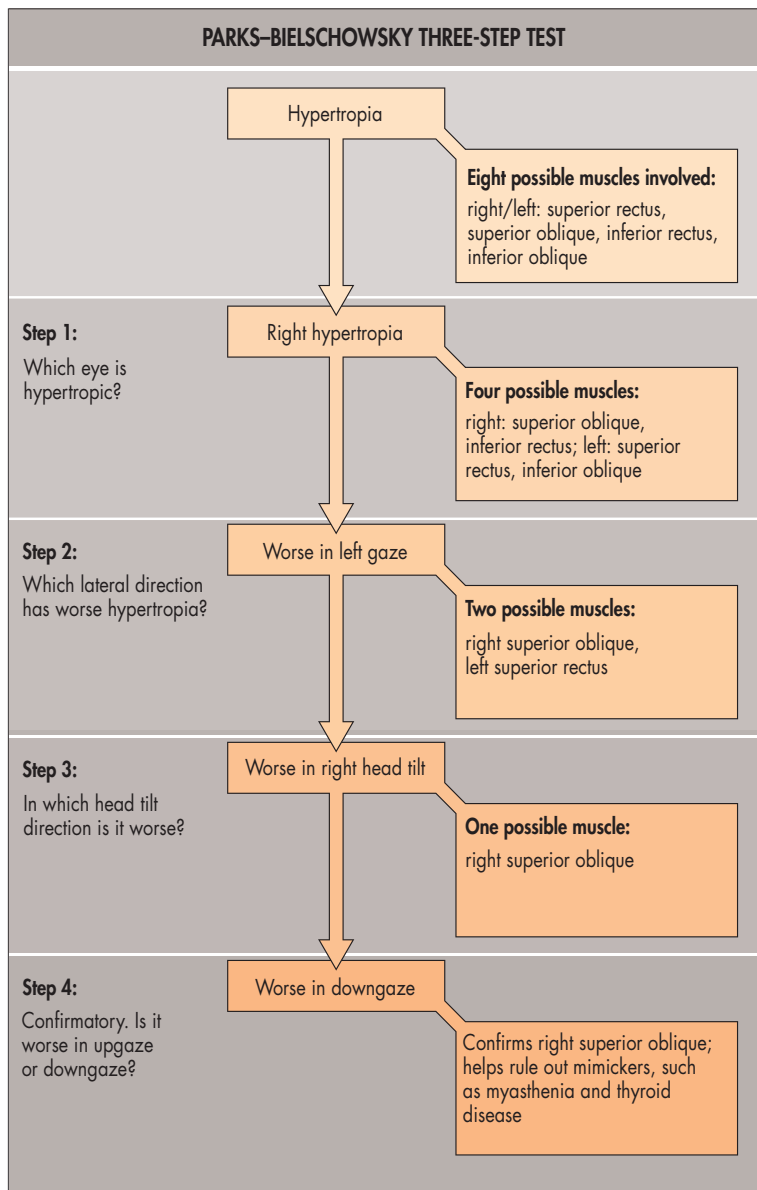

Recurrent sixth nerve palsy may occur as a benign syndrome in children or as a presentation of skull base tumor, and remission of a sixth nerve palsy may occur in either.<sup>6-9</sup> A hypoplastic Dorello's canal has also been reported as a cause of recurrent sixth nerve palsy in children.<sup>10</sup>

Although each series reviews patients differently, some generalizations are apparent from reports of isolated and nonisolated sixth nerve palsy.<sup>1,2,11-18</sup> In adults, an isolated sixth nerve palsy is more likely to be ischemia than a nonisolated sixth nerve palsy, which is more likely

**Fig. 9.16.2** Right Sixth Cranial Nerve Palsy Evaluated by the Maddox Rod Test. A Maddox rod is placed in front of the patient's right eye. Subjective deviation between the light and the line is noted by the patient in different positions of gaze. An esodeviation greatest as the patient looks to the right is consistent with a right lateral rectus muscle weakness.

**Fig. 9.16.3 Parks–Bielschowsky Three-Step Test.** In a patient who has a vertical deviation because of a weakness in a single muscle, this three-step test determines which muscle is weak. Step four confirms that the correct muscle has been identified and helps to rule out other causes of vertical deviation.

inflammation, tumor, trauma, or aneurysm. Additionally, tumor is a more common cause of sixth nerve paresis in young adults and children than in older patients.<sup>19</sup>

### Isolated Fourth Cranial Nerve Palsy

A fourth nerve or trochlear palsy manifests with an isolated, vertical, diagonal, or cyclotorsional diplopia that is worse when looking down and to the side opposite the lesion. It is the most common cause of vertical diplopia. Examination using the Parks–Bielschowsky three-step test (Fig. 9.16.3) shows a hyperdeviation that is worse on contralateral gaze, as well as ipsilateral head tilt. A fourth step that demonstrates that the deviation is worse in downgaze than upgaze is confirmatory. With time, spread of comitance may develop. Double Maddox rod testing shows excyclotorsion (Fig. 9.16.4)—if the excyclotorsion is  $>10^\circ$ , fourth nerve paresis is likely to be bilateral.

### Isolated Third Cranial Nerve Palsy

Patients who have third nerve palsy have a history of horizontal and/or vertical binocular diplopia, ptosis, and/or complaints of enlarged pupil or difficulty in focusing, with involvement of accommodation (Fig. 9.16.5); various combinations of these may occur.

The major causes of isolated third nerve palsy can be categorized by vasculopathic infarction, vasculitic infarction (as in giant cell arteritis [GCA]), compressive (usually from aneurysm), trauma, meningeal inflammation (e.g., with infection or tumor), ophthalmoplegic migraine, or

**Fig. 9.16.4 Double Maddox Rod Test for Excyclotorsion.** A red Maddox rod is placed in front of the right eye and a white Maddox rod in front of the left eye in a trial frame or phoropter. In a patient who has vertical diplopia, one line is above the other. With excyclotorsion, the two lines are not parallel but cross each other. One of the Maddox rods is then rotated until the two lines appear parallel. The degree of rotation required (in this case about  $12^\circ$ ) to make the lines parallel determines the degree of excyclotorsion.

demyelination. Other rare causes include complication of internal carotid artery dissection or occlusion<sup>20,21</sup> or toxicity of chemotherapy.<sup>22</sup>

Several series have looked at the causes of isolated and nonisolated third nerve paresis.<sup>10,13,14,16–18,23–25</sup> From these studies, third nerve paresis is associated more frequently with aneurysm than are fourth or sixth nerve pareses. Ophthalmoplegic migraine is only associated with a third nerve paresis. As with the sixth nerve paresis, isolated lesions are more often ischemic than nonisolated ones.

In vasculopathic third nerve palsy, pain often precedes the onset of ptosis or diplopia, the pupillary reaction is usually spared, and the pupil does not become enlarged. However, in up to 53% of cases, the pupil may be involved, usually with less than 1 mm of anisocoria.<sup>26–28</sup> Clinical associations include diabetes, hypertension, or other atherosclerosis risk factors. The natural course of a vasculopathic, isolated third nerve palsy is one of recovery over weeks to months, usually 3 months. The pupil is spared because the infarction occurs in the center of the nerve, and the pupillary fibers are located in the nerve periphery where there is good collateral blood supply.

Compression of the third nerve from an expanding aneurysm at the junction of the internal carotid and posterior communicating arteries is a true neuro-ophthalmic emergency. Such compressions are usually painful and almost always involve the pupil. However, numerous case reports of isolated third nerve palsy caused by expanding aneurysms show that the pupil may be spared initially.<sup>29</sup> Often, these patients have only partial ptosis and extraocular muscle involvement, and, with very rare exceptions, the pupil becomes involved within 1 week of symptom onset. This situation is one of the few life-threatening emergencies in neuro-ophthalmology, and appropriate diagnosis and treatment are lifesaving.

In contrast to acute third nerve palsy, a slowly progressive third nerve palsy that involves the pupil usually is a sign of an enlarging cavernous sinus lesion.

What has been called “ophthalmoplegic migraine” in the past is likely a misnomer. This refers to a syndrome that consists of migraine-type headache and a third nerve palsy; the pupil is usually involved. Most patients (82% in one series) have an antecedent worsening in migraine severity that precedes the oculomotor paresis and is intense, continuous, and located in the orbital region.<sup>30</sup> As the paralysis reaches its maximum, the headache begins to recede. The initial presentation is usually in childhood, multiple attacks may occur, and a family history of migraine is often present. The third nerve palsy may last from hours to weeks, and permanent deficits occur after repeated attacks.<sup>31</sup> Magnetic resonance imaging (MRI) shows enlargement and enhancement of the third nerve as it exits the brainstem, which is more prominent during the attack.<sup>32</sup>

**Fig. 9.16.5 Isolated Third Nerve Palsy in the Setting of Herpes Zoster Ophthalmicus.** At the time of acute illness. Note the presence of herpes zoster lesions in the distribution of the first division of the fifth nerve. Third nerve palsy consists of ptosis, adduction, elevation, and depression deficit with preserved abduction.

A case of recurrent postviral oculomotor paresis at age 11 months and 39 months has been described, with corticosteroid response and enhancement of the cisternal portion of the oculomotor nerve during the episodes.<sup>33</sup> Other causes of isolated third nerve palsy in the subarachnoid space include trauma, infectious, and neoplastic meningitis.

Aberrant regeneration may occur with recovery of a third nerve because of a structural lesion, but not an ischemic lesion. The abnormal activation of one part of the third nerve is found when another part should be in action. For instance, if fibers originally destined for the medial rectus now supply the levator palpebrae superioris or innervate the pupil, then on adduction of the eye the lid elevates (so-called lid-gaze dyskinesia) or the pupil constricts, respectively. This may give rise to pupillary light-near dissociation. Another common pattern of aberrant regeneration is elevation of the eyelid on downgaze, referred to as pseudo-Von Graefe phenomenon, because fibers destined for the inferior rectus now go to the levator palpebrae superioris. Co-contraction of vertically acting muscles may limit vertical excursion of the eye and be associated with retraction of the globe.

Primary aberrant regeneration refers to the findings above, but with no antecedent third nerve palsy. This suggests a compressive lesion of the third nerve that slowly evolves with ongoing recovery to produce the aberrant regeneration without clinical realization of a third nerve palsy. This occurs most often from internal carotid artery aneurysms, meningiomas, or neurinomas in the cavernous sinus.

Rarely, aberrant regeneration may occur between the sixth and third nerves. For example, on attempted abduction, the lid elevates and the eye adducts. This has been described after trauma with initially complete ophthalmoplegia.

### Divisional Third Cranial Nerve Palsy

The third nerve divides in the anterior cavernous sinus into a superior and inferior division. Either division may be affected by lesions, most commonly structural in the anterior cavernous sinus or orbit. A superior division third nerve palsy manifests with an isolated elevation deficit and ptosis of one eye. A characteristic example is caused by an ophthalmic artery aneurysm. An inferior division third nerve palsy may cause mydriasis and an adduction and depression deficit without ptosis or elevation deficit. Divisional palsies have been described as far posteriorly as the anterior midbrain, likely because fibers have segregated into different portions of the nerve at this point. In addition, cases exist of benign, remitting pareses of either division of the third nerve.<sup>34</sup>

## Nonisolated Cranial Neuropathies

When an ocular motor nerve paresis is accompanied by additional findings, the approach to evaluation changes. Associated findings suggest the localization and character of the lesion. Long-tract findings, alterations in consciousness, or other cranial neuropathies result from brainstem lesions, and these are covered in Chapter 9.15. When there is only cranial nerve involvement, the likely localization includes the subarachnoid space, cavernous sinus, and orbit. Proptosis, chemosis, and visual loss occur with orbital lesions, and these are covered in Chapter 12.10.

In this section, nonisolated cranial neuropathies are reviewed. They are subdivided into categories of multiple cranial neuropathies, bilateral cranial neuropathies, and lesions in the subarachnoid space that may cause both multiple unilateral or bilateral cranial neuropathies.

### Multiple Cranial Neuropathies

In contrast with isolated mononeuropathies, involvement of more than one ocular motor nerve rarely results from vasculopathic lesions. The involvement of multiple nerves enables localization of the responsible lesion, usually in the cavernous sinus, superior orbital fissure, or orbital apex. In numerous series, common causes include tumor, inflammation, trauma, and aneurysm.<sup>14,16,17</sup> Because the first division of the fifth cranial nerve may also be involved in such lesions, pain may be a prominent feature.

Typically, fourth nerve paresis is associated with hyperdeviation, most noticeable when the eye is adducted. In the presence of a third nerve paresis, the eye does not adduct, which makes it difficult to determine the presence of a coexisting fourth nerve paresis. In this situation, the eye is examined carefully for intorsion of the globe on attempted downgaze by visualization of a conjunctival vessel, from which secondary action of the fourth nerve is assessed (Fig. 9.16.6).

On occasion, the third and fourth cranial nerve nuclei may be involved together in the brainstem, usually with other neurological deficits. These cranial nerves may be involved together in the subarachnoid space also, as discussed below.

Because the sixth nerve crosses along the petrous apex, a syndrome that includes sixth nerve palsy, facial pain, hearing loss, and (sometimes) facial paralysis may occur. This is known as Gradenigo's syndrome and may result from infectious mastoiditis, tumor, trauma, aneurysm of the petrosal segment of the internal carotid artery, or inferior petrosal sinus thrombosis. Petrous bone fractures involve combinations of the fifth, sixth,

seventh, and/or eighth cranial nerves and other findings of hemotympanum, Battle's sign (mastoid hematoma), and CSF otorrhea.

The cavernous sinus consists of a plexus of veins. Within the venous plexus lies the sixth nerve, and within the lateral wall of the cavernous sinus lies the third nerve, fourth nerve, first division of the fifth nerve, and, posteriorly, the second division of the fifth nerve. Within the cavernous sinus, the sympathetic fibers form a nerve plexus along the carotid artery (Fig. 9.16.7).

**Fig. 9.16.6 Demonstration of Intact Fourth Cranial Nerve in the Presence of a Third Nerve Paresis.** (A) The patient's right eye is exotropic from a complete third nerve palsy. (B) However, an intact fourth nerve is noted on attempted downgaze because of incyclotorsion of the eye. This is best seen by comparison of the conjunctival vessels in (A) with their position in (B) on attempted downgaze.

The superior orbital fissure contains the same nerves as the anterior cavernous sinus. Therefore, the signs and symptoms of cavernous sinus and superior orbital fissure lesions may be the same. The findings include involvement of any of the above cranial nerves in isolation or in various combinations, including the second division of the fifth nerve if a lesion is in the posterior cavernous sinus. The pupil may be involved, spared, or appear spared with concomitant oculosympathetic and parasympathetic involvement. Various degrees of pain may be involved and, if pain is severe, "painful ophthalmoplegia syndrome" is diagnosed.<sup>35</sup>

Broad categories of diseases that involve the cavernous sinus include neoplasms, inflammation, infection, vascular lesions, and trauma.<sup>36–38</sup> Neoplastic lesions include local metastatic disease from nasopharyngeal cancer, olfactory neuroblastoma, adenoid cystic carcinoma, cylindroma, ameloblastoma, and squamous cell carcinoma, or disease that spreads from distant lesions, which includes carcinoma, sarcoma, multiple myeloma, and lymphoma. Local spread of benign tumors includes pituitary adenoma, meningioma, craniopharyngioma, neurilemmoma, and epidermoid tumor. Chordomas, chondromas, and giant cell tumors may also spread in the cavernous sinus. Meningiomas may arise in the cavernous sinus itself. Neuromas, neurofibromas, or schwannomas may occur on the gasserian ganglion or the other cranial nerves.

Pituitary apoplexy is a clinical syndrome caused by sudden enlargement in a pituitary tumor as a result of acute hemorrhage or edema. Previous symptoms may have been present, but the lesion can also present acutely. Features are variable and include acute and severe headache, diplopia with ophthalmoplegia from cavernous sinus involvement, visual loss from optic nerve, chiasm, or tract involvement, meningismus from hemorrhage into the subarachnoid space, and endocrine insufficiency.

Inflammatory lesions may be both infectious and noninfectious. Bacterial infections may cause cavernous sinus thrombosis, which causes a unilateral or bilateral cavernous sinus syndrome, proptosis, and chemosis associated with signs of fever, depressed mental status, and signs of sepsis. Direct extension of infection or a mucocoele from the paranasal sinuses may cause compression of the cavernous sinus.

Mucormycosis is a life-threatening infection that may affect the cavernous sinus, superior orbital fissure, or orbit. Multiple cranial neuropathies may occur relatively rapidly in a predisposed patient who is diabetic or immunosuppressed. Often an indicative eschar is seen in the nose. An occlusive vasculitis may occur, affecting the brain or eye. A high index of suspicion is required to make the diagnosis.

Aspergillosis also may involve the orbital apex or cavernous sinus. Rarely, other infections, such as syphilis or tuberculosis, may affect the cavernous sinus. Herpes zoster, usually ophthalmic but even with cervical involvement, may be followed by abnormalities of the cavernous sinus. Typically, an isolated ocular motor nerve becomes affected following involvement of the first division of the fifth cranial nerve.<sup>39,40</sup> Occasionally, multiple cranial nerves are affected.

Inflammatory, noninfectious lesions include sarcoidosis, Wegener's granulomatosis, eosinophilic granuloma, and the idiopathic Tolosa–Hunt

**Fig. 9.16.7 Anatomy of the Cavernous Sinus.** Coronal and lateral views. (From Kline LB. The Tolosa–Hunt syndrome. *Surv Ophthalmol* 1982;27:79–95.)

**Fig. 9.16.8 Dural Arteriovenous Fistula.** (A) Patient had diplopia that resulted from a left sixth nerve palsy, Horner's syndrome, proptosis, chemosis, and injection with arterIALIZATION of the conjunctival vessels. (Pupils are pharmacologically dilated.) (B) Arteriogram demonstrates filling of the cavernous sinus and a huge dilated superior ophthalmic vein in the arterial phase of an external carotid artery injection in the same patient.

syndrome; the last causes painful ophthalmoplegia of combinations of the ocular motor nerves, most frequently the third nerve. The pain is described as "gnawing" or "boring" and may precede ophthalmoplegia. Other findings include Horner's syndrome, proptosis, optic nerve involvement, fifth nerve (divisions 1–3) involvement, or seventh nerve palsy.<sup>35,41,42</sup> The symptoms last for days to weeks and spontaneous remissions occur, with or without residual deficits. Recurrences may occur at intervals of months to years.

Vascular causes of a cavernous sinus syndrome include carotid artery aneurysm, cavernous sinus thrombosis, direct carotid artery to cavernous sinus fistula, and dural arteriovenous fistula. Intracavernous carotid artery aneurysms are saccular aneurysms that develop most commonly from atherosclerosis. They cause slowly progressive ophthalmoplegia through enlargement, often with aberrant regeneration, and may cause an acute carotid cavernous fistula if they bleed. Trauma to the internal carotid artery may also cause a direct carotid cavernous fistula.

A direct carotid cavernous fistula can cause cavernous sinus syndrome, as well as headache, facial pain, severe proptosis, chemosis, and injection of the eye, with arterIALIZATION of conjunctival and episcleral vessels. Often pulsatile tinnitus and an orbital bruit occur, and retinal venous engorgement and hemorrhage, central retinal vein occlusion, retinal ischemia, serous retinal or choroidal detachment, and anterior ischemic optic neuropathy may also be seen. Intraocular pressure may be elevated and angle-closure or neovascular glaucoma may develop.

A less serious fistula results from a dural arteriovenous connection in which multiple dural vessels that come off the arterial system connect directly with the cavernous sinus. This occurs most often in older women and has a subacute or chronic course. The findings include the above cranial neuropathies, as well as proptosis, orbital bruit, and conjunctival injection, none as severe as those associated with a direct internal carotid cavernous fistula. The more subtle clinical picture means that these patients are often misdiagnosed with chronic conjunctivitis, episcleritis, or thyroid ophthalmopathy (Fig. 9.16.8).

Involvement of the sixth nerve with loss of tearing and sometimes sensory loss in the second division of the fifth nerve localizes a lesion to the sphenopalatine fossa, usually from metastatic tumor or nasopharyngeal carcinoma. Poliomyelitis may involve one or more cranial nerves, most often the sixth cranial nerve.

**Fig. 9.16.9** Magnetic resonance image (with gadolinium) of a patient with bilateral sixth cranial nerve palsy. The palsy resulted from intracranial hypotension after lumbar spine surgery. Note the diffuse enhancement of the meninges.

### Bilateral Ophthalmoplegia

Bilateral ophthalmoplegia, a unique variant of the syndrome of multiple cranial neuropathy, refers to the involvement of more than one of the above cranial nerves, including at least one on each side. This implies a lesion that is large enough to cause deficits bilaterally or is situated in a location such that bilateral cranial nerves are involved.

Mobius' syndrome is a congenital syndrome associated with bilateral sixth nerve or horizontal-gaze paresis and seventh nerve (facial nerve) paresis and other deficits, which may include tongue atrophy, hand and face deformities, and other malformations. Bilateral sixth nerve paresis is seen in posterior fossa or clivus lesions, including clivus meningioma, chordoma, chondroma, or chondrosarcoma, as well as spread of nasopharyngeal carcinoma. An epidural hematoma in this area can also cause bilateral sixth nerve paresis.<sup>43</sup> This may occur because the two sixth nerves run adjacent to each other along the clivus or because sixth nerve palsies are nonlocalizing.

Increased intracranial pressure of any cause may produce unilateral or bilateral sixth nerve palsy by downward pressure and shift of the brainstem. This is because the sixth nerve is fixed as it exits the pons and as it pierces the dura to enter Dorello's canal under the petroclinoid ligament. Papilledema inevitably is present. Myelography, spinal anesthesia, or even lumbar puncture can cause a bilateral sixth nerve paresis through a similar mechanism of downward shift of the brainstem from a pressure differential. However, there is intracranial hypotension, and diffuse enhancement of the meninges may be seen on MRI (Fig. 9.16.9). Dolichoectasia or aneurysm of the basilar artery also may cause unilateral or bilateral sixth nerve paresis. In bilateral sixth nerve paresis, ischemic causes are less frequent and trauma is more common than in unilateral cases.<sup>15</sup> Bilateral sixth nerve palsy must be distinguished from nonorganic convergence spasm.

Bilateral fourth nerve paresis may be seen after head trauma. Trauma likely involves the nerves in the area of decussation in the anterior medullary velum. Bilateral fourth nerve paresis also may be seen with hydrocephalus, tumor, arteriovenous malformation, or demyelinating disease.

With bilateral fourth nerve paresis, right hyperdeviation in left gaze or right head tilt and left hyperdeviation in right gaze or left head tilt occur. In primary position, depending on the relative symmetry of the bilateral fourth nerve paresis, orthophoria, or right or left hyperdeviation may occur. An additive effect of exocyclodeviation occurs, with the result that greater than 10° of exocyclotorsion is often seen. Because a tertiary action of the superior oblique muscle is abduction, loss of action of both superior obliques in downgaze causes a relative esodeviation in downgaze, which results in a characteristic "V"-pattern horizontal deviation.

Rarely, bilateral simultaneous ophthalmoplegia may have a vasculopathic cause.

### Subarachnoid Involvement

With subarachnoid involvement, signs of multiple cranial nerve involvement may occur on one or both sides, as well as headache, stiff neck, photophobia, and fever. Causes include subarachnoid hemorrhage, trauma,

infectious or neoplastic meningitis, idiopathic intracranial hypertension (pseudotumor cerebri), tumors on the sixth nerve, or tumors in the clivus that compress the sixth nerve. With elevated intracranial pressure, papilledema occurs.

Infectious meningitis may arise from bacterial, fungal (mainly cryptococcal), tuberculous, or syphilitic causes, or from Lyme disease. Inflammatory meningitis occurs with sarcoidosis.

Patients with human immunodeficiency virus (HIV) may develop cranial neuropathies, associated with mostly secondary infectious causes (toxoplasmosis and cryptococcus) and with numerous other symptoms and signs. In one series of patients with HIV and neurological involvement, 17% had sixth nerve palsy, 9% third nerve palsy, and 1% fourth nerve palsy.<sup>44</sup>

### Nonisolated Third Cranial Nerve Palsies

Nonisolated third nerve palsies occur in the subarachnoid space and are accompanied by meningeal signs. The processes are similar to those described above—mainly infectious, neoplastic, or traumatic. However, one additional nonisolated third nerve syndrome occurs with uncus herniation through the tentorium, with large hemispheric mass lesions (e.g., tumor, hemorrhage, or infarct with edema). The patient has a corresponding neurological deficit and is lethargic. The third nerve is compressed against the tentorial edge, petrous ridge, and clivus by the uncus of the temporal lobe. Usually, pupillomotor fibers are involved first. Rarely, upward herniation from a mass in the posterior fossa may cause a third nerve palsy.

## DIAGNOSIS

Although the above history and examination techniques should enable specific identification of the dysfunctional nerve(s), the associated findings (“the company it keeps”) are perhaps even more critical. Associated findings, such as involvement of other cranial nerves, other neurological deficits, or findings suggestive of an orbital process ultimately help localize the lesion and differentiate the likely causes.

In some instances, the cranial neuropathy is truly isolated to only the third, fourth, or sixth nerve. These cases necessitate a unique approach.

The evaluation of patients for ophthalmoplegia depends on the age of the patient. In infants, a congenital deficit or birth trauma is considered; in children, a postviral syndrome, trauma, or posterior fossa tumor; in young adults, trauma, multiple sclerosis, aneurysm, or arteriovenous malformation; and in older adults, diabetes, hypertension, atherosclerosis, tumor, or GCA.

The character of the onset and progression is an important indicator of etiology. Acute onset occurs with vascular, inflammatory, or traumatic causes. Progressive deficits are consistent with mass lesions, such as tumor or aneurysm. Intermittent symptoms suggest myasthenia gravis.

Although cranial neuropathy commonly results from trauma, such deficits only rarely occur with mild trauma. In these instances, an underlying structural lesion, such as aneurysm or tumor, often is present.<sup>45</sup>

### Isolated Cranial Neuropathies

Isolated cranial neuropathies are occasionally seen with intrinsic brainstem lesions. These are discussed in Chapter 9.15.

#### Isolated Sixth Cranial Nerve Palsy

In a child who has an acquired, isolated sixth nerve paresis, early investigation with MRI is reasonable because of the frequent presentation of tumor with sixth nerve paresis.

In an older person, with or without a history of diabetes or hypertension, an erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), platelet count, blood pressure recording, hemoglobin A1c, and serologies may be indicated. The patient may be followed up clinically, but if no improvement occurs over a few months or if the early clinical features deviate from the expected course, then neuroimaging, preferably with MRI, is required. The imaging must focus on the course of the sixth nerve, including the pons, clivus, petrous apex, cavernous sinus, and orbit. Some experts advocate MRI in all patients with isolated cranial neuropathy because up to 12% may have lesions that may benefit from early treatment, including pituitary apoplexy.<sup>13,46</sup> CSF and nasopharyngeal examination are considered if there is a high suspicion of nonvasculopathic etiology and no other cause is found.

In a young adult, particularly without evidence of hypertension or diabetes, the above serological tests and neuroimaging studies are performed, and, if negative, a CSF examination is a reasonable approach. If no

abnormality is found, the patient is followed up at regular intervals and re-evaluated at 6 months if resolution does not occur.

#### Isolated Fourth Cranial Nerve Palsy

The evaluation of patients affected by isolated fourth nerve paresis depends on the age group and setting. A history of significant trauma or evidence of a congenital fourth nerve paresis with decompensation requires no further workup.

In older patients with vascular risk factors, ESR, CRP, and platelet count are performed to rule out GCA (see Chapter 9.22), and the patient may be followed up clinically. Without this history, blood pressure, blood glucose, ESR, CRP, and platelet count are checked. If no resolution occurs within 6 months, neuroimaging, preferably with MRI, should be performed. Examination of CSF may be considered as well, although, without other neurological symptoms or signs, the diagnostic yield will be low. Some experts advocate early neuroimaging.<sup>13</sup>

In children and young adults who have no history of trauma or evidence to suggest a congenital cause, neuroimaging and a search for vasculitis are indicated. CSF examination is indicated if no clear cause can be established and if the deficit does not resolve.

#### Isolated Third Cranial Nerve Palsy

In adults of vasculopathic age, the most important issue is whether the pupil is involved or not. If the pupil is spared with otherwise *complete* involvement of ocular motility and ptosis, the patient is over 50 years of age, and he or she has diabetes and/or hypertension, a diagnosis of vasculopathic third nerve paresis may be presumed. Since aneurysms that do not at first involve the pupil have been described, the patient is followed carefully for the first week, and if the pupil becomes involved, further evaluation is indicated.<sup>47,48</sup> Some clinicians perform MRI on all isolated cranial neuropathies at presentation, and in particular for a third nerve palsy where aneurysm is a possibility MRI and magnetic resonance angiogram (MRA) or computed tomography (CT) and computed tomographic angiography (CTA) are reasonable.<sup>13</sup> One study found other etiologies in presumed vasculopathic ocular motor palsies in 16.5% of cases. When third nerve palsies and GCA cases were removed, the rate dropped to 4.7%. This might suggest that it is important to image third nerve palsies even when presumed to be vasculopathic.<sup>49</sup>

If the pupil is involved, the appropriate evaluation must be pursued until aneurysm is excluded adequately. The reliability of noninvasive imaging is dependent on the training and experience of the interpreting radiologist.<sup>50</sup> Initially, MRI or, if not available, CT, with and without contrast, is carried out for subarachnoid blood and evidence of aneurysm. If negative, MRA or CTA may show an aneurysm. However, in some centers, the sensitivity of MRA and CTA is not considered sufficient to exclude an aneurysm. In this situation, urgent catheter angiography must be carried out. If an aneurysm is found, emergency neurosurgery or interventional occlusion is necessary to prevent subarachnoid hemorrhage.

There is also controversy surrounding proper testing for the presentation of partial ptosis with ophthalmoparesis, with complete sparing of the pupil. Many investigators evaluate this similarly to a pupil-involving third nerve paresis, whereas others investigators monitor the patient carefully for pupillary involvement. The authors' opinion is that these patients should undergo neuroimaging.

Although aneurysmal compression must be excluded, other masses also cause relative pupillary spared third nerve palsies.<sup>51</sup> Therefore, in addition to MRA or CTA, standard MRI or CT is required.

If a pupil-sparing third nerve paresis does not resolve within the expected 3–6 month period or signs of aberrant regeneration are observed, further workup, including MRI, vasculitis workup, and, if no diagnosis has been confirmed, CSF examination, is indicated.

In children, many cases have a congenital etiology, and no further workup is indicated. In such patients, third nerve palsy often is incomplete and associated with signs of aberrant regeneration. If a difficult delivery was involved, trauma is the most probable cause. In those conditions that are acquired, angiography is likely indicated. Although the youngest reported age for a child with posterior communicating artery aneurysm is 7 years<sup>52</sup>, even infants may have an arteriovenous malformation or cavernous carotid aneurysm causing oculomotor palsy.<sup>53</sup>

If the history is suggestive of so-called ophthalmoplegic migraine, MRI will show enlargement and enhancement of the third nerve.<sup>32</sup>

In adults below the vasculopathic age, all acquired third nerve palsies should be investigated with MRI, blood tests (ESR, Lyme titer, glucose, antinuclear antibody [ANA]) to rule out vasculitis or infection, and CSF examination if no other cause is found.

## Nonisolated Cranial Neuropathies

### Multiple Cranial Neuropathies

The management of patients with cavernous sinus and superior orbital fissure lesions depends on the age of the patient, acuteness of presentation, speed of progression, presence of pain, history of systemic diseases or tumors, and accompanying features. Patients who have fever, somnolence, or a toxic appearance must be evaluated rapidly for evidence of cavernous sinus thrombosis or mucormycosis. Those who seek treatment acutely with prominent vascular features, with arterialization of conjunctival vessels, proptosis, and bruits, must be evaluated for direct carotid cavernous fistula.

The workup includes neuroimaging with MRI, with and without gadolinium. If MRI is contraindicated, CT, with and without contrast, using very thin axial and coronal sections, is indicated. Most often, the structural lesion is imaged by one of these techniques. For a dural arteriovenous fistula or direct fistula, MRA, orbital color doppler imaging, as well as conventional angiography, may be performed. In rare instances, CSF examination is helpful. When appropriate, blood tests, such as level of angiotensin-converting enzyme, and Lyme titer, are considered.

When a mass lesion consistent with tumor is found, metastasis must be considered and the diagnosis established by biopsy of lesions elsewhere. With primary tumors, biopsy of the cavernous sinus lesion is often necessary.

With the onset of painful ophthalmoplegia consistent with idiopathic inflammation, a course of corticosteroids should be considered. A positive response to corticosteroids has been used as diagnostic support for Tolosa–Hunt syndrome. However, since similar responses may occur in association with tumors, such as chordoma, giant cell granuloma, lymphoma, epidermoid, and other inflammatory conditions. This diagnosis must be made with caution as a diagnosis of exclusion. Differential diagnostic considerations for the presentation of painful ophthalmoplegia are listed in [Box 9.16.1](#). Evaluation to exclude the above causes of the cavernous sinus syndrome, as well as numerous other conditions, includes neuroimaging, complete blood count, ESR, rapid plasma reagin, fluorescent treponema antibody, ANA, Lyme titer, serum protein electrophoresis, and, occasionally, nasopharyngeal and CSF examinations. Neuroimaging results may be normal or may show a lesion consistent with inflammation. With recurrent episodes consistent with Tolosa–Hunt syndrome, biopsy of any lesion

noted on neuroimaging is indicated to rule out other entities. In the few cases reviewed pathologically, idiopathic chronic granulomatous inflammation and thickened fibrous tissue is seen.

When a patient with a known or occult pituitary adenoma has acute onset of painful ophthalmoparesis, pituitary apoplexy may be found by demonstration of acute hemorrhage or swelling of the pituitary adenoma on neuroimaging. These patients undergo transsphenoidal hypophysectomy and treatment for possible acute pituitary insufficiency.

To diagnose direct or indirect carotid cavernous fistula, arteriography is the definitive diagnostic procedure. However, MRI and MRA may demonstrate enlargement of the superior ophthalmic vein or the actual fistula. Other helpful procedures include CTA, Doppler ultrasound, orbital color Doppler, and measurement of ocular pulse amplitude. Reversal of flow, arterial pulsations, and arterialization may be demonstrated in the superior ophthalmic vein. Orbital color Doppler results may be as high as 96% sensitive for carotid cavernous fistula with anterior manifestations. However the specificity is low at 41%.<sup>54</sup>

### Bilateral Ophthalmoplegia

Neuroimaging that includes the course of each nerve involved is performed in those who have bilateral simultaneous ophthalmoplegia. If negative, CSF examination is carried out, and serological evaluations for collagen vascular disease, arteritis, syphilis, and Lyme disease, are performed. Wernicke's encephalopathy should be considered in cases of bilateral ophthalmoplegia.

## DIFFERENTIAL DIAGNOSIS

Numerous disorders that affect ocular motility may mimic and appear identical to a cranial neuropathy. These processes include restrictive ophthalmopathies, such as thyroid disease; neuromuscular diseases, such as myasthenia; and polyneuropathies, such as the Miller–Fisher variant of the Guillain–Barré syndrome.

The major examination technique used to exclude a restrictive process is the forced duction examination, in which a forceps or cotton-tipped swab is used to overcome the ductional deficit in the eye. A positive sign of restriction is when the deficit cannot be overcome because of resistance. Another sign of restrictive disease is an elevation of intraocular pressure when the eye moves in the direction of the restriction.

## Isolated Cranial Neuropathies

### Isolated Sixth Cranial Nerve Palsy

The differential diagnosis of a sixth nerve paresis includes Duane's retraction syndrome, thyroid or other restrictive ophthalmopathy, myasthenia gravis, spasm of the near reflex, or breakdown of a previous esophoria.

Duane's syndrome is a congenital abnormality that occurs in three different forms, which share palpebral fissure narrowing and globe retraction when the eye is adducted. Type I consists of an abduction deficit that mimics a sixth nerve paresis, type II consists of an adduction deficit, and type III includes both an abduction and adduction deficit ([Fig. 9.16.10](#)). MRI has revealed the absence of the ipsilateral abducens nerve in type I Duane's syndrome and in some of those with type III. Patients with type II had preserved abducens nerves. Pathologically, there is abnormal development of the abducens nucleus and innervation of the lateral rectus by branches of the oculomotor nuclei. During adduction, co-firing of the medial and lateral recti produces retraction of the globe. Duane's syndrome is bilateral in 18% of cases and familial in 10%.<sup>55,56</sup> Compared to sixth nerve pareses, patients with type I tend to have greater abduction deficit, less esotropia in primary gaze, and less distance–near disparity.<sup>57</sup> But the clearest distinction is that Duane's syndrome, unlike sixth nerve palsy, does not cause diplopia. Spasm of the near reflex is most often a nonorganic, functional disorder in patients who have psychogenic disease or in malingerers, but it rarely is seen in organic disease.<sup>58</sup> It presents with an abduction deficit that arises from substitution of convergence for lateral gaze. The diagnosis is made by finding the other features of the near reflex, mainly miosis, on attempted lateral gaze. Ductions tested with the other eye covered usually are normal.

Restrictive ophthalmopathy of the medial rectus most often results from thyroid disease, which is associated with other orbital signs, such as proptosis, injection, chemosis, lid retraction and lag. Other restrictive processes include trauma and orbital myositis. Forced duction testing result is positive.

Myasthenia may be differentiated on history and examination by the features of fatigability and variability. Evaluation with office testing (ice

### BOX 9.16.1 Differential Diagnosis of Painful Ophthalmoplegia Syndrome

- Trauma
- Aneurysm
  - Intracavernous carotid artery
  - Posterior cerebral artery
  - Basilar artery
- Carotid cavernous fistula
- Cavernous sinus thrombosis
- Tumors
  - Primary intracranial
  - Local or distant metastasis
  - Pituitary apoplexy
  - Meningeal carcinomatosis or lymphomatosis
- Infection
  - Mucormycosis or other fungal infection
  - Herpes zoster
  - Tuberculosis
  - Bacterial sinusitis, mucocoele, periostitis
  - Syphilis
- Inflammation
  - Sarcoid
  - Wegener's granulomatosis
  - Tolosa–Hunt syndrome
  - Orbital pseudotumor
  - Giant cell arteritis
  - Ischemic
  - Diabetes
  - Hypertension
- Ophthalmoplegic migraine

**Fig. 9.16.10 Duane's Syndrome (Type III).** (A) Abduction deficit. (B) Adduction deficit, retraction of globe, and narrowing of palpebral fissure on adduction of the right eye. (Adapted from Moster ML. Complications of cancer therapies. In: Miller N, Newman NJ, editors. Walsh & Hoyt's Neuro-ophthalmology, 5th ed. Baltimore: Williams & Wilkins; 1997.)

test, sleep test, or Tensilon test), acetylcholine receptor antibody, and single-fiber electromyography establishes the diagnosis.

Patients who have worsening congenital esophoria or compensated esotropia, often in times of stress or infection, may give a history consistent with sixth nerve palsy. However, a relatively comitant deviation and the presence in old photographs favor this diagnosis.

### Isolated Fourth Cranial Nerve Palsy

The differential diagnosis of isolated fourth nerve paresis includes myasthenia gravis, thyroid ophthalmopathy and other orbital restrictive processes, Brown's syndrome, skew deviation, and overaction of the inferior oblique muscle associated with congenital strabismus. Associated signs in thyroid ophthalmopathy and myasthenia gravis are noted above for sixth nerve paresis.<sup>59</sup> Skew deviation, a supranuclear vertical deviation that results from brainstem disease, is often associated with other neurological findings. There may be a comitant or incomitant pattern of deviation that does not correspond with the three-step pattern of a fourth nerve paresis. A decrease in vertical hypertropia by greater than or equal to 50% from the upright position to the supine position may also suggest skew deviation.<sup>60</sup> The ocular tilt reaction, a form of skew deviation that most closely mimics a fourth nerve paresis, appears with hypotropia, head tilt toward the hypotropic eye, and conjugate torsion toward the hypotropic eye.<sup>61</sup> In addition, excyclotorsion may not be present with myasthenia, skew deviation, and thyroid disease, but is invariably present with an isolated fourth nerve paresis.

Brown's syndrome causes diplopia because of an elevation deficit in adduction, in which the involved eye is hypotropic; forced duction test is positive. When congenital, this syndrome results from a short or tethered superior oblique tendon, but the acquired syndrome may be a result of tenosynovitis, adhesions, metastasis, or trauma. Brown's syndrome actually mimics an inferior oblique paresis; the latter may be differentiated by concomitant overaction of the superior oblique muscle, an "A"-pattern horizontal deviation, and a negative forced duction test.

### Isolated Third Cranial Nerve Palsy

The differential diagnosis of isolated third nerve palsy is not as lengthy as for fourth and sixth nerve palsies because of the many structures innervated by the third nerve and the characteristic findings. Nonetheless, in the absence of pain or pupil involvement, myasthenia gravis must be considered. Restrictive ophthalmopathy may mimic parts of a third nerve paresis but does not involve the pupil. If caused by thyroid ophthalmopathy, lid retraction is more commonly present than ptosis, and there are often other orbital findings. A supranuclear lesion may involve ptosis and an elevation deficit but shows improved motility with oculoccephalic maneuvers.

## Nonisolated Cranial Neuropathies

It is important in the diagnosis of simultaneous palsies of the ocular motor nerves to differentiate these from ophthalmoparesis that arises from orbital inflammatory disease, such as Graves' ophthalmopathy or orbital pseudotumor, ocular myopathies (e.g., chronic progressive external ophthalmoplegia), disorders of neuromuscular transmission (e.g., myasthenia gravis or botulism), and polyneuropathies (e.g., Miller-Fisher variant of Guillain-Barré syndrome). Demyelinating disease, basilar artery ischemia or aneurysm, skull base tumors, Wernicke's encephalopathy, and supranuclear gaze palsies also must be included in the differential diagnosis of nonisolated cranial neuropathies.

## TREATMENT

Besides treatment for the specific cause of the cranial neuropathy, the symptom of diplopia must be addressed. Acutely, occlusion of either eye using a patch or opaque tape over glasses is treatment good option, particularly in patients who are expected to recover. With chronic diplopia, prisms may be helpful for a subgroup of patients, especially when the deviation is relatively comitant. Eventually, with chronic, stable deviations, strabismus surgery (see Chapter 11.13) may be useful.

Some clinicians have used botulinum toxin injections, particularly early in fourth or sixth nerve paresis, to promote more rapid fusion during recovery. However, botulinum treatment does not hasten ultimate recovery.<sup>62</sup> In chronic cranial nerve paresis, botulinum treatment may be used; for instance, in fourth nerve paresis, it may be injected into the ipsilateral inferior oblique or the contralateral inferior rectus.

## Nonisolated Cranial Neuropathies

The Tolosa-Hunt syndrome is exquisitely sensitive to corticosteroids—pain resolves almost immediately, and ophthalmoplegia resolves subacutely with 60–80 mg/day of oral prednisone with a gradual taper. However, recurrences may not respond as well.

Direct internal carotid cavernous fistulas are treated with intra-arterial balloon occlusion of the connection between the carotid artery and cavernous sinus. Occasionally, neurosurgery is required, with occlusion of the carotid artery both above and below the site of the fistula.

Dural arteriovenous fistulas may be followed clinically if no threat to vision exists. In over 50% of patients, the fistula spontaneously undergoes thrombosis and resolves, particularly after angiography. In addition, training the patient to perform occlusion of the carotid artery intermittently during the day with digital pressure (provided no serious cerebrovascular disease is present) may allow for spontaneous thrombosis to occur. On some occasions, spontaneous thrombosis may be associated with retinal vein occlusions and visual loss. If there is a threat to vision, selective arteriography with occlusion of the feeder vessels is performed. Catheter angiography is also important to assess the presence of cortical venous drainage, which is associated with an increased risk of intracranial hemorrhage.

# Disorders of the Neuromuscular Junction

9.17

Lauren T. Phillips, Deborah I. Friedman

**Definition:** A disorder of the neuromuscular junction, caused by an antibody-mediated autoimmune attack on postsynaptic acetylcholine receptors or the altered presynaptic release of acetylcholine.

## Key Feature

- Ocular or generalized muscle weakness.

## Associated Features

- Ptosis and ocular motility disturbances.
- Facial, trunk, and limb weakness.
- Speech and swallowing dysfunction.
- Respiratory compromise.
- Autonomic nervous system dysfunction.

## MYASTHENIA GRAVIS

### Introduction

Of all the disorders of the neuromuscular junction (Table 9.17.1), myasthenia gravis is the most common.<sup>1</sup> It is a disorder caused by an antibody-mediated autoimmune attack on the acetylcholine (ACh) receptors at the neuromuscular junction. The hallmark of myasthenia gravis is fluctuating muscle weakness that worsens with exertion and improves with rest. Ocular manifestations, such as ptosis and diplopia, are present frequently at onset and eventually are present in most patients. A subset of patients has only ocular symptoms.

### Epidemiology and Pathogenesis

The prevalence of myasthenia gravis is rising, largely as a result of longer lifespans. An estimated 8–10 cases per 1 million persons occur annually.<sup>2</sup> Women are affected twice as frequently as men. The incidence has one peak in the second and third decades, affecting mostly women, and another in the sixth and seventh decades, involving mostly men. However, the disease can occur at any age. Patients age greater than 50 years are more likely to require hospitalization for myasthenia gravis.<sup>3</sup> Younger patients, who are more likely to have thymic hyperplasia, often have human lymphocyte antigen (HLA-B8 and HLA-DR3) patterns. There is an association with HLA-B7 and HLA-DR2 in patients age greater than 40 years.<sup>4,5</sup> The neuromuscular junction is composed of the motor axon terminal, the synaptic cleft, and the postsynaptic surface of the muscle cell (Fig. 9.17.1), in which deep infoldings occur. ACh is stored in vesicles in the cytoplasm of the nerve terminal and mediates neuromuscular transmission. Depolarization of the axon by an action potential causes release of ACh into the synaptic cleft by calcium-dependent, voltage-dependent exocytosis. Ordinarily, more ACh than is needed to produce neuromuscular transmission is released, and this creates a safety factor. Once released, the ACh diffuses across the synaptic cleft to the postsynaptic folds.

The postsynaptic folds contain the ACh receptors and acetylcholinesterase, the enzyme that hydrolyzes ACh. In general, the receptors are located on the tips of the folds, and acetylcholinesterase is concentrated deeper within the synaptic folds. When two ACh molecules bind to a receptor, conformational changes occur, and an ion channel opens, resulting in a local depolarization and subsequent muscle contraction. An additional safety factor exists at this level because the potential generally exceeds the threshold required for depolarization of a muscle fiber (end-plate potential). Innervated receptors undergo continuous turnover, with a half-life of 8–11 days.

In myasthenia gravis, the major pathological changes are found at the postsynaptic membrane, with loss and simplification of the postjunctional

TABLE 9.17.1 Disorders of Neuromuscular Transmission

Disorder	Cause	Location	Defect	Symptoms	Treatment
Myasthenia gravis	Autoimmune	Postsynaptic	Antibodies to ACh receptor	Ptosis, diplopia Weakness, improves with rest	Pyridostigmine (Mestinon), corticosteroids, immunosuppressants; thymectomy
Botulism	<i>Clostridium botulinum</i> infection	Presynaptic	Impaired ACh release	Ptosis, diplopia, tonic pupils, accommodative impairment, bulbar weakness, cholinergic blockade	Respiratory support Antitoxin BabyBIG-IV (Infantile)
Lambert–Eaton myasthenic syndrome	Paraneoplastic	Presynaptic	Impaired ACh release	Rarely ptosis, diplopia, proximal muscle weakness Autonomic dysfunction	Treat malignancy 3,4-diaminopyridine, corticosteroids, immunosuppressants
Organophosphate toxicity	Insecticides Chemical warfare	Synaptic	Inhibits acetylcholinesterase	Rapid respiratory failure Muscle twitching then paralysis Mental status changes Pupillary miosis	Atropine, pralidoxime
Black widow spider ( <i>Latrodectus mactans</i> ) bite	$\alpha$ -Larotoxin	Presynaptic	Increased ACh release	Autonomic hyperactivity, vasoconstriction Painful, rigid abdomen	Calcium, magnesium, atropine, antivenin; warming
Tick paralysis	Toxic	Presynaptic	Impaired ACh release	Irritability, pain, paralysis Respiratory paralysis Late signs—unreactive pupils, ophthalmoplegia	Remove tick, supportive measures
Scorpion toxin	Toxic	Presynaptic	Increased ACh release	Agitation, respiratory failure, blurred vision, abnormal eye movements, jerking of extremities, autonomic dysfunction	Calcium, atropine, antivenin, supportive measures

ACh, acetylcholine.

folds, reduced numbers of ACh receptors, and a widened synaptic cleft. New receptors are synthesized, but they are not incorporated into the damaged postsynaptic membrane, which results in loss of receptors at the junction. The synapses of patients with myasthenia gravis contain about one third the number of ACh receptors found in those of healthy controls. The number of receptors seems to parallel the severity of weakness. With a reduced number of receptors, the end-plate potential is inadequate to generate contraction of some muscle fibers; this produces the characteristic muscle weakness. Normally, a decline (“rundown”) occurs in the amount of ACh released by successive muscle contractions. At myasthenic junctions, the rundown produces progressive failure of neuromuscular transmission because of the reduced number of receptors. This accounts for the muscular fatigability that is the hallmark of the disease.

The muscular abnormalities in myasthenia gravis result from an antibody-mediated process that likely originates in the thymus gland. The antibodies both accelerate the rate of degradation of ACh receptors and block ACh-binding sites. B cells produce the autoantibodies, but T cells also are important in the autoantibody response of myasthenia gravis. In myasthenia gravis, T and B cells produced by the thymus gland are more responsive to the ACh receptor compared with their counterparts in peripheral blood. Of patients who have myasthenia gravis, 75% have thymic abnormalities; of these, 85% have thymic hyperplasia, and 15% have thymomas. Perhaps the strongest evidence for the importance of the thymus gland in the pathogenesis of myasthenia is the effectiveness of thymectomy.<sup>6</sup>

Congenital myasthenic syndromes (CMSs) are rare, inherited disorders caused by various genetic defects of the neuromuscular junction. Patients may present with fatigable weakness of ocular, extraocular, and limb muscles. Electrodiagnostic testing typically shows a decremental response to slow repetitive nerve stimulation or characteristic compound motor action potential after-discharges. CMSs are not antibody-mediated and

therefore are not treated with immunotherapy. Rather, treatment options include quinidine sulfate, fluoxetine, salbutamol, or acetylcholinesterase inhibitors, depending on the region of defect.<sup>7</sup> CMS will not be discussed in further detail here.

## Ocular Manifestations

Ocular symptoms, that is, ptosis and diplopia, are present at onset in about 70% of patients and eventually are present in 90%. Ptosis, either isolated or associated with extraocular muscle involvement, often is the first symptom. The ptosis may be unilateral or bilateral, symmetrical or asymmetrical, and often it is more pronounced as the day progresses. Of the patients with myasthenia gravis, 15% have only ocular symptoms and signs.<sup>1</sup>

Involvement of the extraocular muscles varies from single-muscle paresis to total ophthalmoplegia. Myasthenia gravis may simulate ocular motor nerve palsy, unilateral or bilateral internuclear ophthalmoplegia, or gaze palsy. When the levator palpebrae superioris also is involved, the disease may mimic pupil-sparing third nerve palsy. Patients experience diplopia, which usually fluctuates throughout the day; sometimes the disease produces vertical separation of images, and at other times, it causes horizontal diplopia. The diplopia may be intermittent. Other motility abnormalities include saccadic dysmetria and decreased final saccadic velocity, small “quiver” eye movements, and gaze-evoked nystagmus.<sup>8</sup> Nystagmus occurs because of muscle fatigue; isolated nystagmus as a sign of myasthenia gravis is rare. For practical purposes, the pupils are normal in myasthenia gravis. Although anisocoria, impaired accommodation, and sluggishly reactive pupils have been described, the abnormalities are subtle and not clinically significant.

## Diagnosis

The diagnosis of myasthenia gravis is usually suspected from the patient’s symptoms and the results of the physical examination. The presence of ptosis and extraocular muscle weakness that either fluctuates or does not conform to any pattern of ocular motor nerve paresis raises the suspicion of myasthenia gravis. Many ocular signs may be present on physical examination. With unilateral ptosis, the other eyelid may appear retracted, exhibiting Hering’s law of equal innervation. If the ptotic eyelid is lifted manually, the ptosis worsens on the contralateral side (“see-saw ptosis”) (Fig. 9.17.2). This finding is not exclusive to myasthenia but is frequently present in patients who have the condition. Cogan’s lid twitch and Beinfang’s signs demonstrate the rapid recovery and easy fatigability of the levator. When the patient looks down for 10–20 seconds and then rapidly looks up to primary position, the upper eyelids often overshoot (retract) and then settle back into a stable position; a downward drift of the lids or several twitches may be observed (Cogan’s) or after 5 seconds of forced lid closure (Beinfang’s). Prolonged upgaze produces muscle fatigue, with eyelid droop or downward drift of the eyes. As the patient attempts repeated large-amplitude saccades, slowing of the eye movements may occur with repetition. Ice placed on a ptotic lid may prolong the time for which the ACh receptor channels open and produce clinical improvement. The ice test is a sensitive and specific test for myasthenia gravis.<sup>9–11</sup>

With generalized myasthenia gravis, muscle strength testing reveals weakness, usually more prominent proximally. Individual muscles weaken with repetitive testing; the strength improves after a brief period of rest.

A combination of physical examination, pharmacological tests, blood tests, and electrodiagnostic tests is often needed to confirm the diagnosis. If a demonstrable, measurable abnormality is present on the examination, administration of an acetylcholinesterase inhibitor produces increased strength of myasthenic muscles.<sup>12</sup> The most commonly used agent is intravenous edrophonium (Tensilon®) because of its rapid onset

**Fig. 9.17.1 Neuromuscular Junctions.** In myasthenia gravis, acetylcholine is released from presynaptic vesicles and diffuses across the synaptic cleft to the postsynaptic receptors. Acetylcholinesterase, located deep within the synaptic folds, hydrolyzes acetylcholine. There is also a simplification of the postsynaptic site with a reduced number of receptors. (From Drachman DB. Myasthenia gravis. *N Engl J Med* 1994;330:1797–810.)

**Fig. 9.17.2 Myasthenia Gravis.** (A) Right ptosis and compensatory left upper lid retraction. (B) On looking right note right abduction deficit and left lid retraction to compensate for right ptosis. (C) On sustained upgaze, right upper lid becomes fatigued.

of action (30 seconds) and short duration of action (5 minutes). Baseline readings are taken for the pulse, blood pressure, and the physical sign to be measured (e.g., measurement of the palpebral fissures and levator function or quantitation of subtle motility deficits using a Maddox rod or Hess screen).<sup>13</sup> The patient should be warned of potential side effects, including diaphoresis, abdominal cramping, nausea, vomiting, salivation, and lightheadedness.

Although the complication rate is very low, the most dangerous complication of intravenous edrophonium administration is heart block, and atropine sulfate should be made available immediately (0.4–0.6 mg, adult dose).<sup>14</sup> Alternatively, patients may be pretreated with intramuscular or subcutaneous atropine. The patient's pulse and blood pressure are monitored during the test. Ten milligrams are drawn into a tuberculin syringe. After administration of an initial test dose of 2 mg intravenously, the patient is observed for 1 minute while the pulse is monitored. Most patients with ocular myasthenia improve with the test dose. If no improvement and no adverse reaction occur, an additional 4 mg is administered. The remaining 4 mg can be used if no effect is seen. The presence of eyelid fasciculations indicates that an adequate dose was injected. Intramuscular neostigmine (Prostigmin®) is useful in children who may not cooperate with intravenous injections. Neostigmine (1.5 mg for adults or 0.04 mg/kg for children, mixed with 0.6 mg atropine sulfate) produces observable effects within 15 minutes; peak action occurs 30 minutes after injection.

A safe alternative to the edrophonium test is the sleep test.<sup>15</sup> After the baseline deficit has been documented, the patient rests quietly with eyes closed for 30 minutes. The measurements are repeated immediately after the patient “wakes up” and opens the eyes. Alternatively, an ice pack is placed over closed lids for a few minutes. Improvement after rest is characteristic of myasthenia gravis.

A serum assay for anti-ACh receptor antibodies should be obtained for all patients who have suspected myasthenia gravis. Antibody titers do not correlate with the severity of the disease and typically are not serially measured to assess response to immunotherapy. The binding antibody is obtained most commonly, being detected in approximately 90% of patients who have generalized myasthenia gravis and 70% of patients who have ocular myasthenia. Blocking antibodies are present in approximately 60% of patients who have generalized myasthenia and 50% of patients who have ocular disease, and rarely are present (1%) without binding antibodies. Muscle-specific kinase (MuSK) antibodies are present in 40% of patients with generalized myasthenia when other antibodies are not detected. However, MuSK antibodies are rarely detected in purely ocular disease.<sup>16</sup> Several other antibodies have been described in association with myasthenia gravis; the clinical significance of these is being characterized. Serological testing for antilow density lipoprotein receptor-related protein 4 (anti-LRP4), anti-titin, and antiryanodine receptor (anti-RyR) antibodies is commercially available. Seronegative patients comprise 10%–15% of those with myasthenia gravis.<sup>1</sup> These patients should have antibody tests repeated within 12 months following presentation, and the clinical diagnosis should be reassessed, as needed.

Electrophysiological tests are useful for the diagnosis of myasthenia gravis if other tests are inconclusive. Repetitive supramaximal motor nerve stimulation (1–3 hertz [Hz]) produces a progressive decremental response of the compound muscle action potentials during the first four or five stimuli. This technique shows abnormalities in 40%–90% of patients who have myasthenia gravis and results are more likely to be positive with severe disease. Single-fiber electromyography (SFEMG) demonstrates “jitter,” which indicates the variability of propagation time to individual muscle fibers supplied by the same motor neuron. Intermittent “blocking” caused by failure of conduction at the neuromuscular junction also may occur. The sensitivity of SFEMG is approximately 90%.<sup>17</sup> In particular, SFEMG of the superior rectus and levator palpebrae muscles is extremely sensitive for the detection of ocular myasthenia gravis.<sup>18</sup> Conversion from ocular to generalized disease is less likely with normal SFEMG findings of the upper extremities.<sup>19</sup>

Because 10%–15% of patients who have myasthenia gravis have a thymic tumor, chest imaging (contrast-enhanced computed tomography or magnetic resonance imaging) is mandatory, even for patients with solely ocular findings (Fig. 9.17.3). Plain chest radiography alone is not adequate for this purpose. The persistence of a thymus gland in a patient age greater than 40 years or an increase in size on serial imaging studies raises the suspicion that a thymoma is present.

Other testing is directed toward associated systemic autoimmune diseases and treatment. Because 5% of patients who have myasthenia gravis have coexistent thyroid disease, thyroid function tests should be obtained for all patients. Complete blood count, antinuclear antibody analysis, and

**Fig. 9.17.3 Computed Tomography of the Chest With Contrast Enhancement.**

A large, multilobulated thymoma in a 32-year-old man with ocular myasthenia gravis. The mass is in proximity to the aortic arch and the ascending aorta. A focal calcification is present anteriorly. The patient's ptosis and diplopia remitted after removal of the thymoma.

erythrocyte sedimentation rate typically are tested in patients who have confirmed myasthenia gravis. If treatment with corticosteroids is planned, diabetes and tuberculosis should be excluded. Neuroimaging of the brain may be considered for atypical cases that are antibody negative and refractory to treatment (Table 9.17.2).

## Systemic Associations

Generalized myasthenia gravis develops in the majority of patients. The nonocular symptoms include facial weakness, jaw weakness dysarthria, dysphagia, nuchal muscular weakness, and limb weakness. Erector spinae involvement may cause inability to maintain an erect posture. Most patients feel tired with reduced stamina. In severe cases, weakness of the muscles of the chest and diaphragm produces dyspnea and orthopnea. A pronounced drop in the vital capacity leads to myasthenic crisis, which requires mechanical ventilation and aggressive treatment.

Approximately 12% of neonates born to mothers with myasthenia develop transient neonatal myasthenia gravis as a result of maternal transmission of autoantibodies through the placenta; these trigger independent antibody production by the infant. Affected neonates have generalized weakness, with difficulty eating, respiratory weakness, a poor cry, and facial weakness, which are noticed shortly after birth. The symptoms last for several weeks and then resolve without recurrence. Treatment is supportive.

Thymic enlargement and thymoma frequently are present in patients who have myasthenia gravis. Other autoimmune disorders, such as thyroid disease, systemic lupus erythematosus, neuromyelitis optic spectrum disorders, and pernicious anemia, are found with increased frequency in patients with myasthenia gravis.

## Treatment

The major therapies for myasthenia gravis are as follows:

- Acetylcholinesterase inhibitors.
- Immunosuppression.
- Symptomatic treatment of ocular abnormalities.
- Avoidance of agents that worsen neuromuscular transmission.
- Thymectomy in some cases.

Acetylcholinesterase inhibitors raise the safety factor for neuromuscular transmission by preventing the degradation of ACh. These agents provide symptomatic improvement in muscle weakness. However, because of their rapid effectiveness and lack of long-term side effects, they often are the first agents used in the treatment of myasthenia. Pyridostigmine (Mestinon®), the most commonly used drug, has a duration of action of 2–8 hours. It is most useful for the treatment of systemic weakness of myasthenia gravis and may not improve the diplopia. The usual starting dose is 30–60 mg every 4 hours while the patient is awake. Larger doses or more frequent dosing intervals may be used, as needed. Above 120 mg every 3 hours, no additional effectiveness is likely and a risk exists

TABLE 9.17.2 Differential Diagnosis of the Neuromuscular Junction

Disorder	Pupils	Ocular Motility	Lids	Other Ocular Findings	Other Systemic Findings
Myasthenia gravis	Normal	Fluctuating ophthalmoparesis	Ptosis Cogan's lid twitch sign	—	Fluctuating weakness that improves with rest
Thyroid eye disease	Normal	Restricted EOM Positive forced duction testing	Lid retraction Lid lag Lid edema	Conjunctival infection Keratoconjunctivitis sicca Exophthalmos Optic neuropathy	Symptoms of hyperthyroidism may be present
Botulism	Dilated, poorly reactive Light–near dissociation	Ophthalmoparesis	Ptosis	—	Limb weakness, bulbar signs Respiratory failure Urinary retention Constipation
Lambert–Eaton myasthenic syndrome	Usually normal	Usually normal	Usually normal	Keratoconjunctivitis sicca	Autonomic and limb weakness that improves with repetitive testing
Guillain–Barré syndrome	Normal or poorly reactive	Normal or ophthalmoparesis	Ptosis	—	Facial diplegia Limb weakness +/- sensory symptoms Areflexia Respiratory failure
Progressive external ophthalmoplegia	Normal	Slowly progressive Symmetrical ophthalmoparesis	Slowly progressive Ptosis	May have pigmentary retinopathy	Varying degrees of multisystem involvement due to mitochondrial disorder

EOM, extraocular movement.

of cholinergic crises. A delayed-release preparation taken at bedtime is useful for patients who have profound weakness upon awakening in the morning. The most common side effects from these agents are gastrointestinal disturbances (nausea, diarrhea, cramping) and muscle twitching. Overdosing results in sialorrhea, blurred vision, and worsening weakness (cholinergic crisis). It may be difficult to distinguish between cholinergic crisis caused by medication and worsening of the disease. Diplopia often does not improve with pyridostigmine and may be treated with immunosuppressive agents.<sup>20</sup>

Thymectomy is indicated for all patients who have a thymoma. A study of patients age 18–65 years with generalized nonthymomatous myasthenia gravis, with disease duration of less than 5 years, showed that thymectomy is beneficial for patients with ACh receptor antibody–positive myasthenia gravis. Extended transsternal thymectomy improved clinical outcomes over a 3-year period.<sup>6</sup> Guidelines and consensus statements recommend thymectomy for patients with early-onset generalized myasthenia gravis, usually those with detectable muscle antibody tests. Thymectomy may be considered in seronegative or ocular myasthenia gravis if the disease is refractory to standard immunotherapy.<sup>20,21</sup> ACh receptor antibodies status does not seem to influence the efficacy of the surgery, but active ectopic rests of thymic tissue portend a worse prognosis.<sup>22</sup> A transsternal approach is preferable because it allows for adequate visualization of the thoracic cavity and total thymus removal. Robotic techniques shorten the operative time and hold promise as less invasive techniques for extended thymectomy; ectopic rests of thymic tissue may remain undiscovered with use of the less invasive transcervical technique.<sup>23</sup> The morbidity and mortality rates from thymectomy are quite low. Because any surgical procedure may worsen myasthenia, some patients benefit from a short course of plasmapheresis preoperatively. Radiotherapy to the thymus gland is not effective.

Immunosuppressants, mainly cytotoxic agents and corticosteroids, treat the disease directly and are generally employed in patients who do not improve satisfactorily with acetylcholinesterase inhibitors. It may be several weeks to months before these medications take effect. Corticosteroids, most commonly prednisone, are used most frequently, and various dosing strategies are employed. Daily administration of high doses (60–100 mg) may produce substantial worsening within the first 2 weeks after initiation and should be used with caution, particularly in corticosteroid-naïve patients. Other regimens use increasing, daily, low doses of prednisone, or alternate-day dosing. Alternate-day dosing has the advantage of fewer side effects, and many patients who have purely ocular symptoms improve on a low dosage (20–30 mg) of alternate-day therapy. Corticosteroid monotherapy may reduce the risk of generalization in patients with ocular myasthenia gravis, although this issue remains controversial.<sup>20,24,25</sup> The risks of long-term prednisone administration include peptic ulcer, osteoporosis, femoral neck fracture, diabetes, skin breakdown, weight gain, and cushingoid features. Appropriate medical precautions and monitoring are required. To minimize the complication rate, the lowest dosage of prednisone possible should be used, and other immunosuppressant agents added, if needed.

Azathioprine, cyclosporine, and mycophenolate mofetil are utilized for the long-term management of myasthenia gravis and may be used in combination with prednisone and pyridostigmine.<sup>1,2</sup> These medications

have fewer long-term side effects compared with prednisone. Rituximab is reserved for patients with severe disease.<sup>2</sup> However, rituximab is well tolerated and effective in treating myasthenia gravis, particularly in patients with MuSK antibodies.<sup>26</sup> Blood counts, liver function, and renal function must be monitored, with a small possibility that a neoplasm will develop after many years of treatment. Plasmapheresis effectively reduces circulating autoantibodies. It is typically reserved for patients in myasthenic crisis or is used preoperatively for thymectomy in patients who have severe weakness. Improvement is rapid, but transient. Like plasmapheresis, intravenous immunoglobulin produces rapid improvement through a difficult period of myasthenic weakness (400 mg/kg per day for 5 days).<sup>2</sup> Patients in myasthenic crisis require aggressive respiratory support, often need intubation and mechanical ventilation, and are best managed in the intensive care unit.

As a rule, ptosis typically responds to treatment but diplopia may be refractory. Ocular symptoms can be treated symptomatically as other therapies are initiated, or when these are ineffective. Lid crutches or eyelid tape may be beneficial for patients who have ptosis, but ptosis surgery should be reserved for patients who are stable over long periods of time and refractory to other treatments. Diplopia is managed using patching or prisms; strabismus surgery is inappropriate for patients who have active myasthenia gravis.<sup>20</sup>

Medications that lower the safety factor of neuromuscular transmission should be avoided in patients who have myasthenia. Penicillamine causes a myasthenic syndrome that may be associated with autoantibody production. Many antibiotics decrease the production or release of ACh, including the aminoglycoside agents (streptomycin, neomycin, kanamycin, gentamicin, tobramycin, amikacin, viomycin), bacitracin, polymyxins (polymyxin A and B, colistin), and the monobasic amino acid antibiotics (lincomycin and clindamycin). Rarely, worsening of myasthenia occurs with erythromycin or following iodinated contrast dye administration. All neuromuscular blocking agents, such as botulinum toxin, curare, and depolarizing agents, should be used with caution. Chloroquine, lithium, and magnesium affect both presynaptic and postsynaptic transmission. Antiarrhythmic agents, including procainamide and quinidine, can cause or worsen myasthenia gravis. Phenytoin, beta-blockers, cisplatin, phenothiazines, statins, and tetracyclines may have similar effects.

## Course and Outcome

Despite its ominous name, myasthenia gravis is seldom fatal; most patients experience remission or good control of their symptoms with treatment. Of those patients who have only ocular symptoms and signs at onset, 10%–20% undergo spontaneous remission and 50%–80% develop generalized disease, almost always within 2 years of onset of the disorder.<sup>27</sup> The majority of patients who continue to have only ocular symptoms 2 years after presentation never develop generalized disease.<sup>1</sup> Patients who have ocular myasthenia who are 50 years of age or older are more likely to progress to generalized myasthenia, whereas a younger age at onset carries a better prognosis.

In adults, the disease is most labile during the first 10 years; most deaths occur during the first year. The long-term prognosis is poorer when

a thymoma is present. When death is caused by myasthenia gravis, usually it is because of respiratory failure with secondary cardiac dysfunction.<sup>28</sup>

## BOTULISM

### Introduction

Botulism is a potentially life-threatening disorder caused by the toxin of *Clostridium botulinum*. Three types exist—food-borne, wound, and infantile. The clinical picture is characterized by rapidly evolving cranial nerve and respiratory weakness with autonomic dysfunction. Associated symptoms include hyposalivation, dysphagia, dysarthria, respiratory failure, muscular weakness, constipation, urinary retention, nausea, and vomiting.

### Epidemiology and Pathogenesis

Botulism, caused by the neurotoxin elaborated by *Cl. botulinum*, may take many forms. Its site of action is the presynaptic nerve terminal, where it prevents the release of ACh. The preformed toxin may be ingested, as in food-borne botulism, or gain access by wound infection. Alternatively, the bacterium or spore may colonize the gastrointestinal tract, as in infant botulism. Inhaled botulism via aerosolization of the toxin is a potential bioterrorism weapon.<sup>29</sup>

At least eight types of toxin have been described, but only three forms commonly affect humans. Type A botulism is usually the most severe form of the disease. In the United States, an estimated 145 cases of botulism are reported yearly—15% food-borne, 65% infant botulism, and 20% wound.<sup>29</sup>

Historically, classic or food-borne botulism was caused by inadequately cleaned, smoked, salted, or dried fish or meat. Contemporary risk factors include commercial or home-prepared condiments, vegetables, nonacid foods, and preserved raw fish.<sup>29</sup> Plastic food storage bags and containers provide a near-perfect anaerobic environment for growth of *Cl. botulinum*. Vehicles for food-borne botulism vary by region worldwide.<sup>29</sup>

Infant botulism occurs during the age range 2–6 months in previously healthy infants. The course is subacute and may be difficult to diagnose until the child becomes severely ill. The classic source of infection is honey. Transmission of spores from adults to infants is possible from soil contamination of clothing. A similar infection can be seen in adults who have achlorhydria, following gastrointestinal operations, and who have blind loops of the bowel.

Wound botulism was once an uncommon form of botulism but is increasing in incidence as a result of intravenous heroin abuse and cocaine abuse associated with necrotic nasal passages.<sup>30</sup>

### Ocular Manifestations

Ophthalmic manifestations are not likely to occur in isolation but are part of a systemic illness. Diplopia and ptosis occur with varying degrees of ophthalmoparesis. Internal ophthalmoplegia with accommodation paresis produces blurred vision. The pupils often are abnormal, with a poor reaction to light. Pupillary light–near dissociation may be observed during the acute infection and occasionally persists after recovery.<sup>31</sup> Quivering eye movements have been described. Hypolacrimation is often found.

### Diagnosis

The diagnosis is based on the symptoms and signs, the circumstances of infection, electrophysiological studies, and isolation of the organism or toxin.

When botulism is suspected, stool, gastric aspirate or vomitus, and at least 20 mL of serum should be collected for analysis. If the source of contaminated food is available, it may be submitted to the relevant health department for evaluation. Identification of botulinum toxin in serum and stool is performed using a mouse bioassay. A Tensilon test result is almost always negative. Electrophysiological studies are very helpful and show changes similar to those seen in the Lambert-Eaton syndrome (discussed later).

### Differential Diagnosis

The Guillain–Barré syndrome, Miller–Fisher syndrome, and poliomyelitis resemble botulism clinically. Myasthenia gravis spares the pupils and is more gradual in onset. Tick paralysis, diphtheria, organophosphate toxicity, shellfish toxicity, ischemic locked-in syndrome, and hypokalemic periodic paralysis are other diagnostic considerations.

## Systemic Associations

Symptoms of food-borne botulism begin 12 hours to 8 days after ingestion of the toxin. Typically, the patient is conscious and afebrile. The characteristic systemic symptoms include hyposalivation and respiratory failure, urinary retention, constipation, and vomiting. Limb weakness may resemble that of Guillain–Barré syndrome, with ascending or descending paralysis. The reflexes are often normal or hypoaactive. Prominent bulbar symptoms and cranial nerve palsies may develop. At worst, the patient is “locked in,” unable to move or respond, but fully awake.

In wound botulism, symptoms begin 4–18 days after injury and are identical to those of food-borne botulism.

Infant botulism causes constipation and weakness, with descending paralysis.<sup>32</sup> The infant has a poor suck, a weak cry, and becomes hypotonic. Impairment of extraocular movement, facial weakness, and cranial nerve palsies are common. Dilated pupils, respiratory arrest, and death may follow. The course often is insidious and mistaken for failure to thrive.

### Treatment

The most important aspect of treatment is supportive, with mechanical ventilation, when necessary. If the patient is not allergic to horse serum (pretesting for hypersensitivity is required), heptavalent botulinum antitoxin is administered in a single treatment.<sup>29</sup> Human-derived botulinum immunoglobulin (“BabyBIG-IV”) is effective for treating infant intestinal botulism. Recovery occurs spontaneously as new synapses develop; this may take 6–12 months.

## LAMBERT–EATON MYASTHENIC SYNDROME

### Introduction

First described in 1953 as a triad of muscle weakness, autonomic dysfunction, and hyporeflexia, the Lambert–Eaton myasthenic syndrome (LEMS) shares clinical features with myasthenia gravis. Unlike myasthenia gravis, LEMS is a presynaptic disorder of neuromuscular transmission affecting voltage-gated calcium channels (VGCC).<sup>33,34</sup> This rare disorder is associated with a malignancy, such as small cell lung carcinoma (SCLC) in at least 50% of cases.<sup>33</sup> Symptoms of LEMS typically precede the diagnosis of the neoplasm.

### Epidemiology and Pathogenesis

Median onset of the paraneoplastic form is around age 60 years.<sup>34</sup> Smoking is a risk factor because of the high association with bronchogenic carcinoma. About 3% of patients who have SCLC have LEMS.<sup>33</sup> The non-neoplastic form is associated with pernicious anemia, thyroid disease, Sjögren’s syndrome, and other autoimmune disorders.<sup>35</sup> Myasthenia gravis and LEMS may occur concurrently.

Symptoms are caused by impaired release of ACh from the nerve terminal. End-plate potentials are too small to generate an action potential. Striated muscle, glands, and smooth muscle are affected. Calcium and guanidine increase neurotransmitter release, which results in improved strength.

### Ocular Manifestations

In contrast to myasthenia gravis, ocular manifestations are not prominent. Decreased lacrimation leads to keratoconjunctivitis sicca, which is the predominant ocular complaint. Ptosis and intermittent diplopia may occur. Sluggishly reactive pupils and tonic pupils are infrequent.<sup>36</sup> Slowed saccadic velocities that normalize after exercise have been described. There is one report of a patient with ophthalmoparesis and pseudo-blepharospasm.<sup>37</sup>

### Diagnosis

Rapid onset and progression of symptoms over weeks to months are common in the paraneoplastic form. The nonneoplastic variety has an insidious onset with mild, stable symptoms. Patients generally have proximal muscle weakness and leg pain. Autonomic involvement is present in 80%–96% of cases, which results in dry mouth, constipation, hypohidrosis, impotence, orthostatic hypotension, and urinary retention.<sup>38,39</sup> Unlike myasthenia gravis, muscle strength improves following voluntary contraction or repetitive testing. Paradoxical lid elevation may occur after

prolonged upgaze.<sup>40</sup> The deep tendon reflexes are hypoactive or absent at rest and increase with voluntary muscle contraction.

Electrophysiological studies confirm the diagnosis. Low rates of nerve stimulation (2–3 Hz) produce a decremental response, but high rates (20–50 Hz) cause a two- to 10-fold incremental increase in the compound action potential. SFEMG shows changes similar to those found in myasthenia gravis. The Tensilon test result is negative, and anti-ACh receptor antibodies are not present. VGCC antibodies are found in 85%–90% of patients with LEMS and in 100% of patients with SCLC and LEMS.<sup>39,41,42</sup> Sry-like high-mobility group box antibodies occur frequently in SCLC–LEMS.<sup>33</sup>

## Differential Diagnosis

Disorders that produce proximal muscle weakness may resemble myasthenic syndrome. Myasthenia gravis usually can be excluded clinically, with its prominent ocular and facial involvement. Guillain–Barré syndrome, polymyositis, lumbosacral plexopathies, and polyradiculopathies can be excluded by electrophysiological testing and neuroimaging.

## Systemic Associations

More than 80% of the associated malignancies are SCLCs. Other tumors associated with LEMS include small cell carcinoma of the cervix or the prostate, adenocarcinoma, and lymphoma. Myasthenic syndrome may precede the detection of the malignancy by up to 7 years and rarely follows detection of the tumor.<sup>35</sup> If no malignancy is found, repeated investigations are warranted. Other laboratory testing includes thyroid function tests, complete blood count, erythrocyte sedimentation rate, antinuclear antibodies, anti-Ro, and anti-La (SS-A, SS-B) to evaluate for the association of the nonneoplastic form with pernicious anemia, thyroid disease, Sjögren's syndrome, and other autoimmune disorders.

## Treatment

3,4-Diaminopyridine blocks potassium channels and enhances the release of ACh from the presynaptic nerve terminal. A definite and sustained response to aminopyridines occurs in most patients.<sup>33</sup> Treatment with

corticosteroids and azathioprine, mycophenolate, cyclosporine, rituximab, intravenous immunoglobulin, or plasmapheresis usually leads to improvement in strength if symptomatic treatment is ineffective.<sup>33</sup> It may take several months for immunosuppressants to be effective. Anticholinesterases may be useful. Magnesium may worsen the weakness. Other medications that decrease neuromuscular transmission should be used with caution. Treatment of the underlying carcinoma may produce improved strength.<sup>33</sup>

## Course and Outcome

The presence or absence of malignancy largely determines the prognosis. Those patients who have lung cancer should be screened regularly for recurrence within the first 4 years of diagnosis and advised to stop smoking. Most patients can lead a moderately active lifestyle with treatment but should avoid vigorous exercise.

# Ocular Myopathies

Michelle Y. Wang, Richard M. Rubin, Alfredo A. Sadun

# 9.18

**Definition:** Ocular myopathies involve pathology of the extraocular muscles that results in ophthalmoplegia and other disorders of ocular motility.

## Key Features

- Limitations of motility.
- Inflammation.
- Exophthalmos.
- Pain.
- Diplopia.

## Associated Features

- Some are acquired and of known mechanism (thyroid orbitopathy).
- Some are acquired and consequent to other processes (certain forms of myositis).
- Some are congenital but may not manifest until late adulthood (mitochondrial).

## INTRODUCTION

Diseases that involve metabolic abnormalities, atrophy, infiltration, or inflammation of the ocular muscles may appear as weakness or restriction. Except for thyroid orbitopathy, most of these conditions are uncommon or rare. The three sections of this chapter independently cover mitochondrial myopathies, dystrophic myopathies, and inflammatory and infiltrative myopathies. Thyroid orbitopathy will be discussed in Chapter 12.13.

## MITOCHONDRIAL MYOPATHIES

### Epidemiology and Pathogenesis

Mitochondria are cytoplasmic organelles that produce energy for cell functions, maintenance, repair, and growth through the enzymatic processes of oxidative phosphorylation. A group of neurodegenerative and myopathic syndromes result from disorders of mitochondrial metabolism that cause defects in the energy cycle of susceptible tissues.<sup>1</sup> The tissues most reliant on mitochondrial energy are those of the central nervous system, heart, muscles, kidneys, and endocrine organs. Hence, these tissues are most likely to show various clinical manifestations of mitochondrial dysfunction.

Each mitochondrion possesses 2–10 mitochondrial DNA genomes made up of a closed circle of 16 569 nucleotide base pairs. The mitochondrial DNA encodes for 13 polypeptides essential in oxidative phosphorylation and the production of mitochondrial proteins. Nuclear DNA encodes for an additional 56 subunits of the electron transport chain and for genes required for replication, transcription, and translation of the mitochondrial genes.

Mitochondrial DNA has unique genetics for several reasons, including its cytoplasmic location and the multiple DNA copies that exist in each cell. Mitochondrial DNA is inherited maternally because it is transmitted via oocyte cytoplasm. In addition, new mutations often result in heteroplasmy, a mixed intracellular population of normal and mutant DNA molecules. Also, multiple random and asymmetrical mitochondrial divisions lead to replicative segregation and eventually homoplasmy, such that each cell possesses only pure mutant mitochondrial DNA. Thus, the relative proportion of normal and mutant mitochondrial DNA may vary from cell to cell and from individual to individual.

The variable phenotypic expressions of mitochondrial dysfunction likely arise from interplay of the unique features of mitochondrial inheritance that cause heteroplasmy and homoplasmy, the modifying contribution of nuclear DNA under the influence of Mendelian genetics, the deterioration of mitochondrial function with aging, and the different energy requirements of specific tissues.

The most common mitochondrial disorder to affect muscles is chronic progressive external ophthalmoplegia (CPEO) and its best known subtype, Kearns–Sayre syndrome.<sup>2</sup> Less common mitochondrial myopathies of ophthalmic importance include mitochondrial encephalopathy with lactic acidosis and stroke-like syndrome (MELAS), myoclonic epilepsy with ragged red fibers (MERRF), mitochondrial neurogastrointestinal encephalomyopathy (MNGIE), and the ataxia neuropathy syndromes (ANSs), including sensory ataxia neuropathy dysarthria ophthalmoplegia (SANDO).<sup>3–5</sup>

Mitochondrial disorders that affect tissues other than muscle during early childhood include Alpers' disease, Menkes' disease, and Leigh's syndrome/neurogenic muscle weakness, ataxia and retinitis pigmentosa (NARP). Leber's hereditary optic neuropathy (LHON), the most frequent mitochondrial disorder, manifests later in life.<sup>6</sup> It is the first maternally inherited disorder that has been associated with mitochondrial DNA point mutation. A more in-depth discussion is provided in Chapter 9.9.

## Ocular Manifestations

Patients who have CPEO often exhibit initial bilateral ptosis that is followed by limitation of ductions in all directions and marked delay of saccades. Downward gaze may be spared until late in the course. Curiously, despite ocular misalignment, these patients rarely complain of diplopia. Weakness of the orbicularis oculi and facial muscles is found commonly, and pigmentary retinopathy may be associated.

Kearns–Sayre syndrome, in particular, is characterized by the triad of external ophthalmoplegia, pigmentary retinopathy, and cardiac conduction block during the first or second decade of life (early-onset CPEO). Peripapillary pigment atrophy and salt-and-pepper retinal pigment epithelial changes are most striking in the macula. True bone spicule pigmentary retinopathy as seen in retinitis pigmentosa is not typical in Kearns–Sayre syndrome.<sup>7</sup>

MELAS syndrome manifests with ptosis and external ophthalmoplegia, in addition to the commonly associated visual disturbances, which may include hemianopia or cortical blindness. Eventually, MERRF develops into progressive optic atrophy. MNGIE is characterized by progressive ptosis, external ophthalmoplegia, and glaucomatous-like optic neuropathy.<sup>8</sup> Patients with ataxia neuropathy syndromes, including SANDO, display axonal sensory neuropathy affecting proprioception, variable degrees of cerebellar ataxia and progressive external ophthalmoplegia in about half of cases.<sup>5</sup>

## Diagnosis

The possibility of muscle disease should be considered whenever ophthalmoplegia does not correspond to the pattern of cranial nerve palsy and when there is acquired ptosis. Most diagnoses are made through a process of exclusion and imaging studies.

Diagnoses of mitochondrial disorders often are supported by histopathological and biochemical evidence of mitochondrial dysfunction. Specific identification of an enzyme defect may confirm the diagnosis. Generally, to show abnormalities in patients who have mitochondrial cytopathies, substrates of oxidative phosphorylation from serum and cerebrospinal fluid (CSF), which include glucose, lactate, and pyruvate, and the pH of venous blood during fasting are all measured. Elevation of CSF protein levels also may help in the diagnosis of CPEO and MELAS syndrome.

Electrocardiography should be performed in all patients suspected of mitochondrial cytopathies, to detect any life-threatening cardiac conduction abnormalities. Neuroimaging may help in the assessment for other causes of neurological deficits. In CPEO, magnetic resonance imaging (MRI) of the orbits demonstrates significant symmetrical extraocular muscle atrophy involving all four recti.<sup>9</sup> Migratory waxing and waning of stroke-like lesions with a predilection for the parietal, temporal, and occipital cortex are commonly found on neuroimaging in MELAS syndrome.<sup>10</sup>

Genetic analysis for mitochondrial DNA mutations from blood leukocytes or muscle biopsy may show a characteristic mutation in MELAS syndrome. Poor correlation exists between specific mitochondrial DNA mutations and CPEO because CPEO may exhibit a clinical picture related to a final common pathway of impaired mitochondrial energy production in muscle from a variety of mutations. Myasthenia and diseases of glycolipid metabolism, lysosomal or glycogen storage, peroxisome dysfunction, and acquired viral, toxic, and endocrine myopathies and encephalopathies also must be ruled out. Electromyography helps differentiate myopathic causes from neuropathic causes of muscle weakness.

## Systemic Associations

When ocular findings of CPEO occur in association with other neurological deficits, the term “CPEO plus” is used. Systemic findings of CPEO include short stature, peripheral neuropathy, ataxia, spasticity, somatic muscle weakness, vestibular dysfunction, and deafness.<sup>11</sup> Lactic acidosis resulting from defective aerobic metabolism is often found. Abnormalities of cardiac conduction and of the central nervous system, which include cerebellar dysfunction and elevated CSF protein exceeding 100 mg/dL, are associated with Kearns–Sayre syndrome.<sup>12</sup> Cardiac conduction disturbances have an onset typically 10 years after ptosis appears and may result in sudden death. Endocrine dysfunction may include hypoparathyroidism, diabetes mellitus, hypogonadism, or growth hormone deficiency. In CPEO and Kearns–Sayre syndrome, the brain eventually may undergo spongiform degeneration, with the clinical picture of dementia. Basal ganglia calcifications may occur.

Seizures, vomiting, lactic acidosis, episodes of hemiparesis, and stroke-like events during childhood or early adulthood characterize MELAS. Although partial recovery from these stroke-like episodes is the rule, severe neurological damage eventually results. Typically, MERRF occurs during the second decade of life with myoclonus, followed by ataxia, weakness, and seizures. Progressive ophthalmoplegia with peripheral neuropathy, leukoencephalopathy, and gastrointestinal dysmotility have been reported in MNGIE.<sup>13</sup>

## Pathology

Biopsy of skeletal muscle reveals “ragged red fibers” that stain red or purple using a modified Gomori’s trichrome stain (Fig. 9.18.1). The mitochondria of the involved muscle fibers are concentrated peripherally and may show increased staining for the mitochondrial enzyme succinate dehydrogenase. Biochemical abnormalities of oxidative phosphorylation, such as patchy cytochrome-*c* oxidase deficiency, may be detected by muscle biopsies as well. Orbicularis oculi muscle can mimic mitochondrial cytopathy in normal persons age greater than 40 years and thus diagnosis would still need to be confirmed with skeletal muscle and/or genetic studies.<sup>14</sup>

The ultrastructural appearances of skeletal muscle mitochondria are varied and may show enlarged mitochondria that contain crystal-like inclusions; changes in the number, shape, or regularity of cristae; or emptiness, vacuolization, or triglyceride accumulation within mitochondria (Fig. 9.18.2). The mitochondria often are increased in number and size. Such morphological changes may be found in other muscle disorders, such as the muscular dystrophies or polymyositis. Histopathologically, the retinal findings in Kearns–Sayre syndrome suggest retinal pigment epithelial dysfunction rather than photoreceptor disease.<sup>15</sup>

## Treatment

There is no effective treatment for mitochondrial disorders. However, some trials have shown promising trends. Coenzyme Q10 (CoQ10), essential for normal mitochondrial function and deficient in a proportion of patients who have CPEO and Kearns–Sayre syndrome, has been associated with improved exercise tolerance, cardiac function, and ataxia in some patients with Kearns–Sayre syndrome.<sup>16</sup> CoQ10, along with creatine and lipoic acid, have shown promising results in improving surrogate markers of cellular

**Fig. 9.18.1 MELAS Syndrome.** (A) Complete external ophthalmoplegia in a 20-year-old woman. (B) Microscopic section of degenerated extraocular muscles stained with trichrome shows “ragged red fibers.”

**Fig. 9.18.2** Viewed under an electron microscope, the abnormal mitochondria in a case of chronic progressive external ophthalmoplegia appear as electron-dense and globular. The normal arrangement of cristae is not seen.

energy dysfunction in patients with CPEO, Kearns–Sayre syndrome, and MELAS.<sup>17</sup> Other treatments, such as thiamine, also aim to bypass or enhance oxidative phosphorylation but only occasionally have been shown to improve exercise tolerance, cardiac conduction, or lactic acidosis. CoQ10 and these other treatments do not improve the ophthalmoplegia, retinopathy, or ptosis in patients who have CPEO or Kearns–Sayre syndrome. However, modified CoQ10 has led to second- and third-generation quinones, idebenone, and EPI-743, that have shown promising results in some LHON cases, providing new direction for possible therapy targeting mitochondrial disorders.<sup>18–20</sup>

Complaints that arise from ptosis often are handled by ptosis crutches or a careful surgical approach, in which the lid is raised minimally by addressing the visual obstruction, rather than the cosmetic appearance.

**Fig. 9.18.3** Slit-lamp view of a "Christmas tree cataract" in myotonic dystrophy. Note the iridescent or colored refractile flecks.

Overly aggressive attempts to treat the ptosis may result in exposure keratopathy and corneal ulceration because of weak orbicularis oculi muscles and a poor Bell's reflex. Symptomatic ocular deviations may be treated successfully with strabismus surgery.

Periodic evaluation by a cardiologist is indicated in Kearns–Sayre syndrome. In some instances, placement of a pacemaker for prophylactic pacing or for treatment of symptomatic cardiac block is necessary to prevent sudden death. The systemic use of corticosteroids is contraindicated in Kearns–Sayre syndrome because of the possible precipitation of coma and death from hyperglycemic acidosis.<sup>21</sup> Genetic counseling should be offered to all patients who have mitochondrial cytopathies.

## Course and Outcome

CPEO is a slowly progressive loss of lid and extraocular motor function. The diplopia may or may not worsen because the symmetry of the ophthalmoplegia may prevent strabismus. However, small ptosis correction may be required. In severe cases that have more generalized manifestations, such as in Kearns–Sayre syndrome, retinopathy and cardiac problems may develop. Patients who have MELAS, MERRF, or MNGIE may develop several systemic and neurological deficits.

## DYSTROPHIC MYOPATHIES

### Epidemiology and Pathogenesis

Three forms of muscular dystrophy of ophthalmological importance exist, all of which involve progressive weakness of the skeletal muscles. Myotonic dystrophy, like the other forms, involves difficulties with relaxation of skeletal muscles after contraction. Myotonic dystrophy is an autosomal dominant condition in which the first symptoms usually appear during the teenage years or in young adulthood. Several large pedigrees have been identified.

Oculopharyngeal dystrophy usually develops later in life. The first symptom often is difficulty in swallowing, with ptosis occurring later. A significant French Canadian autosomal dominant pedigree has been identified, in which the original ancestor immigrated to Quebec in 1634.<sup>22</sup> Autosomal recessive and sporadic inheritances also have been reported.

Fukuyama's congenital muscular dystrophy is an autosomal recessive condition most often found in people of Japanese descent. Unlike the other two forms above, in Fukuyama's congenital muscular dystrophy, manifestations and death occur in early childhood.

### Ocular Manifestations

In myotonic dystrophy, abnormalities in the extraocular muscles are accompanied by involvement of other muscles, including the levator muscle, and result in slowly progressive bilateral ptosis. Other ocular findings include cataracts, described as "Christmas tree cataracts" (Fig. 9.18.3) for their multiple refractile colors.

In oculopharyngeal dystrophy, dysphagia is followed soon by bilateral ptosis which, over a period of years, is followed by external ophthalmoplegia

**Fig. 9.18.4** Front View of a Patient Who Has Myotonic Dystrophy. The muscle wasting gives the characteristic drawn appearance of "hatchet facies."

and weakness of the orbicularis. The patient, despite a remarkable lack of ocular motility, may not complain of diplopia because often the limitations of eye movement are so symmetrical that no strabismus occurs.

In Fukuyama's congenital muscular dystrophy, in addition to the weakness of the orbicularis and a strabismus, nystagmus, anterior polar cataracts, optic nerve atrophy, and a chorioretinal degeneration with retinosischisis or detachment occur as well.<sup>23</sup>

## Diagnosis

Electromyography, which demonstrates characteristic spontaneous, high-frequency bursts, confirms diagnoses of all forms of dystrophic myotonias. Furthermore, all dystrophic myotonias are evident clinically by blepharospasm, or the inability of the patient to open the eyes after they have been forcibly closed for some time. Only myotonic dystrophy has intraocular findings, such as "Christmas tree cataracts." Both myotonic dystrophy and oculopharyngeal dystrophy have external ophthalmoplegia, but Fukuyama's congenital muscular dystrophy does not. In all three dystrophies, biopsy reveals characteristic histopathology.

## Systemic Associations

In myotonic dystrophy, involvement of the muscles of the head and neck gives the characteristic narrow, drawn facial appearance or "hatchet facies" (Fig. 9.18.4). Involvement of cardiac muscles may result in congestive heart failure. Dysphagia, constipation, and incontinence are not uncommon. In some cases, mental retardation occurs, and in men, testicular atrophy and premature baldness are frequent. In oculopharyngeal dystrophy, the bulbar musculature is affected frequently and temporalis wasting occurs. Patients have difficulty swallowing without aspirating. Other bulbar and limb girdle muscles become involved later. In Fukuyama's congenital muscular dystrophy, the proximal muscle groups are involved the most. Mental retardation, seizures, severe motor development delay, and cortical blindness are common.

## Pathology

Rows of nuclei run down the centers of the muscle fibers. In myotonic dystrophy, the myofilaments and sarcoplasmic reticulum are disrupted, and accumulations of impaired mitochondria may be found. In oculopharyngeal dystrophy, tubulofilamentous intranuclear inclusion bodies are seen on ultrastructural examination of muscle biopsies. In Fukuyama's syndrome, the same changes are confined largely to the proximal muscle groups.

## Treatment

For all three muscular dystrophies, treatment consists of symptomatic support. The cataracts of myotonic dystrophy may be removed. Foot braces

and other devices are available to provide support for those with foot drop or other skeletal muscle weakness. All patients affected by dystrophic myopathies need to be referred to neurologists.

## Course and Outcome

Progressive atrophy of the skeletal muscles leads to a variety of systemic difficulties. In myotonic dystrophy, the patient develops difficulty climbing stairs and, eventually, even with walking and holding the head up. Vision may be maintained after cataract surgery. In oculopharyngeal dystrophy, dysphagia is most problematic. Difficulty swallowing and many other serious medical problems limit the lifespan of patients with Fukuyama's congenital muscular dystrophy.

## INFLAMMATORY AND INFILTRATIVE MYOPATHIES

### Epidemiology and Pathogenesis

#### *Orbital Myositis*

The most common cause of primary muscle dysfunction is inflammation. Inflammation or secondary ischemia related to swelling (tissue compartment syndrome) may lead to fibrosis and scarring within an extraocular muscle. Orbital congestion may cause a restrictive component. Orbital pseudo-tumor, or idiopathic orbital inflammation, is usually characterized by extraocular muscles involvement in addition to other orbital structures, such as the lacrimal gland and orbital fat.

Idiopathic orbital myositis refers to nonspecific orbital inflammation. This orbital inflammation may extend anteriorly to involve the posterior globe (posterior scleritis) or lacrimal gland (dacryoadenitis), or posteriorly as orbital apex syndrome, superior orbital fissure syndrome, or cavernous sinus, as Tolosa–Hunt syndrome. When orbital pseudo-tumor involves primarily the muscles (myositis), it tends to occur unilaterally (although bilateral involvement may occur up to 25% of the time) in young adults, with women being affected more frequently than men.

A variety of granulomatous, infectious, neoplastic, and vasculitic disorders may masquerade as isolated myositis.

### Ocular Manifestations

Generally, orbital inflammatory diseases are associated with significant extraocular muscle involvement. The myositis may be isolated to a single muscle, but most often it affects several muscles. The pain often is most severe when ductions away from the most affected muscle are attempted. Patients also frequently experience gaze-evoked diplopia. Local orbital signs, such as exophthalmos and injection, are common. Children are more apt to have bilateral orbital involvement, may develop spontaneous orbital hemorrhage, and are less likely to have an associated systemic disease.

### Diagnosis

In orbital myositis, the involved extraocular muscle usually is enlarged on orbital imaging. Enhancement of the muscle, and particularly its tendon insertion into the globe, may help distinguish myositis from thyroid orbitopathy. A careful review of systems is critical to rule out granulomatous inflammatory diseases, thyroid orbitopathy, infection, and neoplasm. The diagnosis of orbital pseudo-tumor or idiopathic orbital myositis is one of exclusion and can be made only after the appropriate investigations have been carried out. In many cases, the clinical picture is sufficiently clear, and a trial of glucocorticoids may be initiated. An orbital biopsy is indicated, especially if the orbital inflammation is refractory to glucocorticoids or returns after the glucocorticoids have been tapered.

### Systemic Associations

Myositis may be associated with systemic inflammatory disease, such as Crohn's disease, systemic lupus erythematosus, rheumatoid arthritis, sarcoidosis, granulomatosis with polyangiitis, Churg–Strauss syndrome, ankylosing spondylitis, and giant cell arteritis.<sup>24</sup>

Infectious myositis may result from orbital cellulitis or trichinosis, but usually the cause is never determined.<sup>25</sup> Orbital cellulitis may be bacterial and originate from the paranasal sinuses, or fungal in association with metabolic acidosis or diabetes mellitus.

Other infiltrative processes such as amyloidosis and lymphoma may limit extraocular muscle relaxation.<sup>26</sup> Neoplasms may extend locally into or metastasize directly to a muscle.<sup>27</sup>

In recent years, immunoglobulin G4 (IgG4)–related systemic disease (IgG4-RD) has gained increasing attention as a multisystem immune-mediated inflammatory condition, which may affect multiple organs, such as the pancreas, salivary glands, and orbits.

### Pathology

In idiopathic orbital myositis, a polymorphous, chronic inflammatory infiltration is the most common finding. In chronic idiopathic pseudo-tumor, large amounts of fibrovascular stroma also may be seen. Pathological differentiation of orbital pseudo-tumor, benign lymphoid hyperplasia, monomorphous lymphoid lesions, and malignant lymphoma may be difficult. Immunological cell markers and gene rearrangement studies can help distinguish these entities. However, 15%–20% of patients who have polyclonal cell markers eventually may develop monoclonal malignant lymphoma.

Various specific causes of myositis have their own characteristic histopathological features. For example, in cases of foreign bodies, granulomatous inflammation with multinucleated giant cells is found. Polymorphonuclear leukocytes are seen in association with various infections. Eosinophilic infiltration is seen in trichinosis or other parasitic infections. An eosinophilic hyaline accumulation often occurs surrounding the blood vessels or in round globules within the extraocular muscles. In orbital myositis with plasma cell or lymphoproliferative infiltration, an associated amyloidosis may occur.

Some of the idiopathic orbital inflammatory cases were later found to be related to IgG4. The hallmarks of IgG4-RD are dense lymphoplasma-cytic infiltrations with predominance of IgG4-positive plasma cells, fibrosis, and obliterative phlebitis.<sup>28</sup> Increased numbers of eosinophils may be seen. An elevated IgG4+/IgG+ plasma cell ratio may be even more helpful than absolute tissue IgG4+ plasma cell counts, which differ depending on the affected organs.

### Treatment

Treatment should be directed to address the underlying cause. Infection and malignancy should be ruled out before initiating corticosteroid therapy. High-dose, daily glucocorticoids usually reverse the disease process effectively and eliminate the pain. Inadequate treatment may result in recurrence, but once the desired effect occurs, the glucocorticoids must be tapered slowly over several weeks or months and discontinued. Nonsteroidal anti-inflammatory drugs are less effective than glucocorticoids but have fewer side effects. Immunosuppressive agents may be used in refractory cases. Rarely, in those patients who do not respond or who become glucocorticoid dependent, low-dose radiation therapy (2000 cGy) may induce remission effectively, but this may lead to secondary neoplasms decades later. However, many inflammatory and infiltrative myopathies initially respond to such treatment, only to recur. Furthermore, treatment may not only obfuscate the natural history of the disease but may make the diagnosis by biopsy more difficult. Hence, it often is prudent to complete the diagnostic workup, which includes orbital biopsy for atypical cases, prior to anti-inflammatory treatment.

### Course and Outcome

Idiopathic orbital myositis usually responds very well to systemic glucocorticoids. In most cases, the diagnostic workup does not yield any causative factor and recurrences are not very common. Such patients do well and show no evidence of any ophthalmological sequelae.

# Nystagmus, Saccadic Intrusions, and Oscillations

Peter A. Quiros, Melinda Y. Chang

# 9.19

**Definition:** Typically involuntary and rhythmic fixation instabilities; nystagmus arises from an inability to maintain fixation due to slow drift, while saccadic intrusions and oscillations result from instability of spontaneous rapid eye movement.

## Key Features

- Inability to maintain or achieve proper fixation.
- Decreased visual acuity.
- Oscillopsia.

## Associated Features

- Central nervous system abnormalities.
- Strabismus.
- Albinism.

## INTRODUCTION

Nystagmus, saccadic intrusions, and saccadic oscillations are fixation instabilities that usually are involuntary and rhythmic. They may impair vision, and many are signs of neurological disease. By recognizing the specific type of nystagmus or instability, the ophthalmologist can localize central nervous system (CNS) as well as peripheral lesions, determine which follow-up tests are appropriate (e.g., magnetic resonance imaging [MRI]), and often initiate treatment.

## EPIDEMIOLOGY AND PATHOGENESIS

Abnormalities of the vestibulo-ocular, otolithic-ocular, smooth pursuit, optokinetic, vergence, and eccentric gaze-holding systems are implicated in most forms of nystagmus.<sup>1</sup>

## OCULAR MANIFESTATIONS

Nystagmus is caused by an abnormality in a slow eye movement system or in the system that holds fixation. Abnormal slow eye movements cause a drift away from the intended fixation target or direction of gaze. A more rapid eye movement in the opposite direction is then initiated to carry the eyes back to the intended position. Nystagmus waveforms can be jerk or pendular (Fig. 9.19.1). If the corrective movements are faster than the drift, the waveform is termed *jerk*. The slow movements are the slow phase, and the refixation saccades are fast phases. The direction of jerk nystagmus is designated by the direction of the fast components; for example, fast components to the right indicate “right-beating” jerk nystagmus. When the corrective movements also are slow eye movements, the waveform is pendular. These represent the two main types of nystagmus. Nystagmus, by definition, must have a slow phase, thus being differentiated from saccadic intrusions.

Saccadic intrusions are caused by abnormalities in the saccadic eye movement system. Abnormal saccades move the eyes away from the intended direction of gaze, and corrective saccades carry the eyes back. In saccadic intrusions, such as square-wave jerks and macrosquare-wave jerks, brief pauses, or intersaccadic intervals, occur between the opposing

**Fig. 9.19.1 Nystagmus Waveforms.** The horizontal dashed lines indicate the intended position of gaze. (A) Jerk nystagmus with slow components of constant velocity. (B) Jerk nystagmus with slow components of exponentially increasing velocity. The flat, slow component portions near the intended gaze position follow the fast components and represent extended foveation periods typical of congenital nystagmus. (C) Jerk nystagmus with slow components of exponentially increasing velocity. Extended foveation periods follow slow movements that bring the eye toward the intended gaze position. (D) Pendular nystagmus. Note that foveation periods are brief compared with those in B and C. (E) Jerk nystagmus with slow components of exponentially decreasing velocity.

saccades (Fig. 9.19.2). In ocular flutter and opsoclonus, no intersaccadic intervals occur. These are not true nystagmus because these conditions have no slow phase.

Normal visual acuity requires a stationary retinal image on the fovea. If fixation instabilities cause movement of the retinal image across the fovea at speeds of a few degrees per second or greater, visual acuity is diminished. Therefore, many types of nystagmus and saccadic oscillations without intersaccadic intervals cause decreased visual acuity. During volitional saccades, images move across the retina, but there is no sensation of movement of the visual surround. In contrast, most types of nystagmus and saccadic oscillations without intersaccadic intervals cause illusory, back-and-forth movements of the visual surround, called *oscillopsia*.

## DIAGNOSIS

Most types of nystagmus and saccadic instabilities can be detected and identified through careful attention to the characteristics of the oscillations, without the aid of eye movement recordings and other specialized equipment. While the patient fixates on a stationary target at distance and at near, the following questions should be addressed:

- Is the drift away from the target a slow eye movement (nystagmus) or a saccade (saccadic instabilities)?

**Fig. 9.19.2 Saccadic Intrusions and Oscillations.** Dashed lines indicate the intended gaze position. (A) Square-wave jerks with intersaccadic intervals. (B) Macrosquare-wave jerks with intersaccadic intervals. (C) Single saccadic pulse and double saccadic pulses. (D) Ocular flutter with no intersaccadic intervals. (E) Macrosaccadic oscillations following a refixation saccade.

- Do slow movements occur in one direction and fast movements in the opposite direction (jerk nystagmus), or are the opposing movements of equal speed (pendular nystagmus)?
- What is the direction of the instability (horizontal, vertical, oblique, or torsional)?
- What is the effect of blocking fixation? Does it increase the nystagmus intensity (vestibular nystagmus), or does it decrease the intensity (congenital nystagmus)?

Frenzel goggles to block fixation or electronic equipment to record eye movements in the dark are helpful but are usually not readily available. Viewing the fundus of one eye with a direct ophthalmoscope while the patient covers the other eye blocks fixation and magnifies motion of the observed fundus caused by abnormal eye movements. The fundus moves in the direction opposite to that of the eye. The direct ophthalmoscope is an excellent instrument that helps detect small-amplitude oscillations, such as voluntary “nystagmus” and superior oblique myokymia.

Further questions to address are as follows:

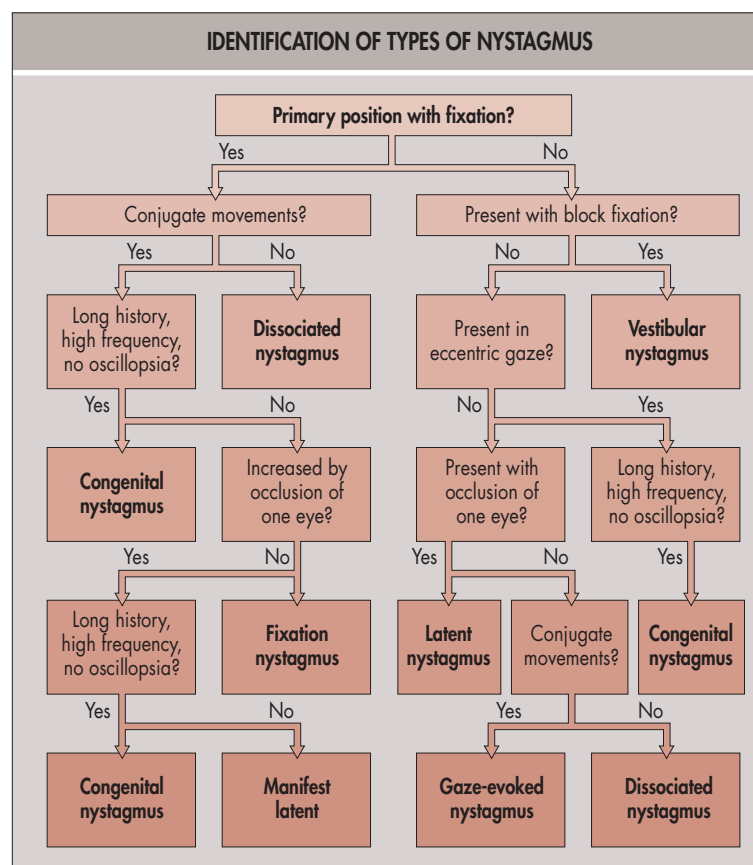

- What is the effect of different gaze positions? Acquired jerk nystagmus generally worsens in the direction of the fast phase.
- Does eccentric gaze change the intensity or the direction of the instability? Congenital nystagmus changes the direction of the fast phase with the position of gaze (i.e., right-beating in right gaze, left-beating in left gaze).
- Is the instability present only in eccentric gaze (gaze-evoked nystagmus)?
- Are the oscillations in both eyes symmetrical, or are they asymmetrical with different amplitudes or directions in each eye (disconjugate nystagmus)?
- If no instability occurs in the sitting upright position, is it present in other positions of the body and head (vestibular nystagmus of benign paroxysmal positional vertigo [BPPV])?

The answers to these questions and information from the patient's history and other physical findings will allow the ophthalmologist to identify the instability. Figs. 9.19.3–9.19.6 are flowcharts that can be used to identify the different types of nystagmus.

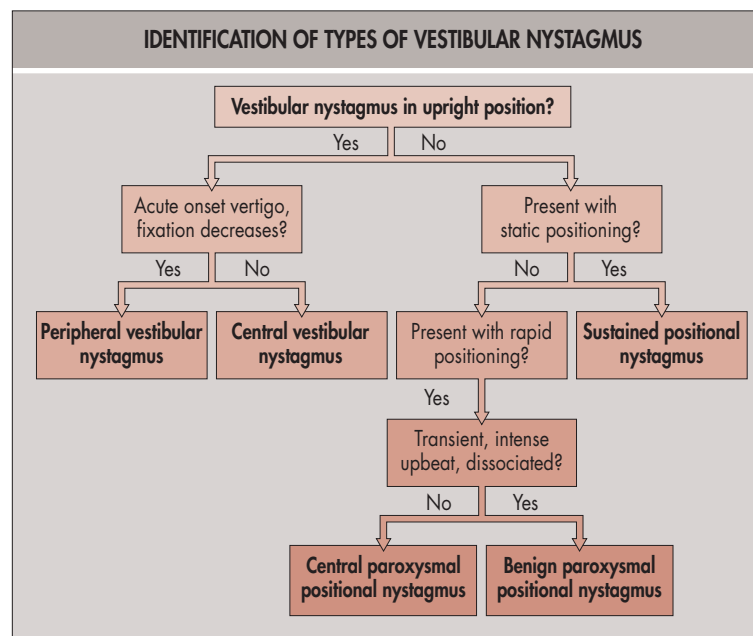

## DIFFERENTIAL DIAGNOSIS

### Congenital Nystagmus

Congenital nystagmus is the most common form of nystagmus, accounting for about 80% of all nystagmus cases. It is also one of several

**Fig. 9.19.3 Identification of Types of Nystagmus.**

**Fig. 9.19.4 Identification of Types of Vestibular Nystagmus.**

common types of nystagmus occurring in children (Table 9.19.1); it is a high-frequency, horizontal nystagmus that begins in the first few months of life (Video 9.19.1). Congenital nystagmus is not pathogenetically associated with other CNS disorders, although it is found frequently in patients who have certain systemic and ocular disorders that impair vision, such as oculocutaneous albinism and ocular albinism (Video 9.19.2). It can be an X-linked recessive, autosomal dominant, or autosomal recessive disorder. The most common genetic cause of X-linked congenital nystagmus is a mutation in the *FMRD7* gene.<sup>2</sup>

The nystagmus waveforms are pendular, jerk, or a combination of the two, and many are complex. Brief intervals often occur when the retinal image is relatively stationary on the fovea, called *extended foveation periods*, which allows better visual acuity. Unlike in vestibular nystagmus, fixation increases the nystagmus intensity, whereas staring and blocking fixation

## IDENTIFICATION OF TYPES OF GAZE-EVOKED NYSTAGMUS

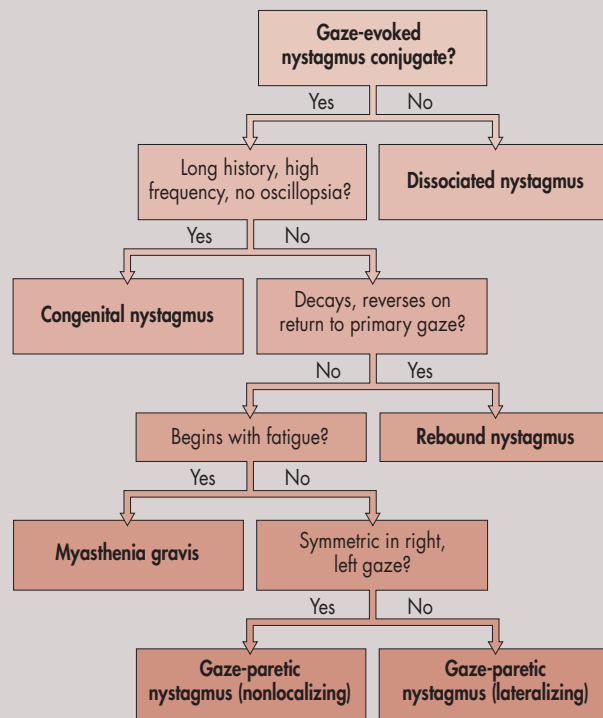

Fig. 9.19.5 Identification of Types of Gaze-Evoked Nystagmus.

## IDENTIFICATION OF TYPES OF DISSOCIATED NYSTAGMUS

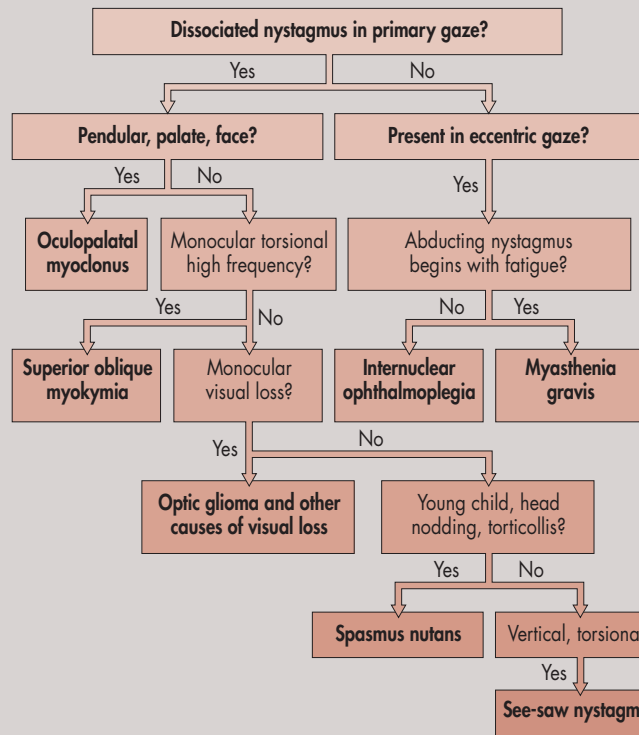

Fig. 9.19.6 Identification of Types of Dissociated Nystagmus.

decrease the nystagmus. In contrast to patients who have acquired types of nystagmus, patients who have congenital nystagmus rarely complain of oscillopsia.

Patients who have congenital nystagmus often exhibit a head turn, which places their eyes into the so-called null point, in which nystagmus intensity is minimized, foveation periods are long, and visual acuity is best. High-frequency, low-amplitude head nodding is seen commonly. The head nodding usually does not improve vision. Congenital nystagmus remains horizontal in vertical gaze and is usually decreased at near with

TABLE 9.19.1 Characteristics and Localizations of Nystagmus in Childhood

Nystagmus	Characteristics	Localization
Idiopathic congenital	Complex waveforms, jerk (increasing velocity slow components), pendular, horizontal, null zone, (face turn, head nodding, no oscillopsia)	Coexisting ocular, visual pathway lesions (not pathogenetic)
Latent/manifest latent	Jerk (decreasing velocity slow components), horizontal, fast components beat toward fixating eye	Coexisting infantile esotropia
Spasmus nutans	Pendular, horizontal, small vertical, torsional, dissociated, high-frequency, (torticollis, head nodding), onset in first year, resolution in 1–2 years	No signs of visual pathway lesions
Monocular visual loss	Pendular, vertical, horizontal, monocular, high-frequency, intermittent, (occasional head nodding)	Gliomas of optic nerve, chiasm or third ventricle, and other causes of visual loss

convergence. The dampening of nystagmus with convergence improves vision, which is one reason why many children who have congenital nystagmus do not need schoolbooks with large-size print. In one form of the nystagmus blockage syndrome, excessive convergence produces an esotropia, fixation of the distant target with the adducted eye, a decrease in nystagmus, and improved vision.<sup>3</sup> In another form, a switch occurs from a congenital nystagmus waveform to a manifest latent nystagmus (MLN) waveform (see the next section) when the adducted eye fixates. In such patients, vision is better with the latter type of nystagmus.

## Latent and Manifest Latent Nystagmus

Latent nystagmus is always associated with strabismus, usually infantile esotropia. In true latent nystagmus, no nystagmus is present with both eyes open (Video 9.19.3). When either eye is occluded, a horizontal jerk nystagmus occurs, the slow components of which are toward the occluded eye and the fast components of which beat toward the uncovered, fixating eye. The shift of fixation is the stimulus for the nystagmus. Electronic eye movement recordings have shown that true latent nystagmus is rare. In most instances, a low-intensity jerk nystagmus (MLN) exists that beats toward the fixating eye without occlusion. Nystagmus intensity increases with occlusion of the nonfixating eye, and the jerk nystagmus reverses direction when the eye that preferentially fixates is occluded. Gaze in the direction of the fast component increases nystagmus intensity, and gaze in the opposite direction decreases the intensity (Alexander's law). Patients who have MLN can have a habitual face turn toward the direction of the fast component, which places the eyes in the opposite direction and improves vision. Congenital nystagmus patients who have jerk nystagmus also can show reversal of the nystagmus direction when each eye is occluded, as a result of a shift in the position of the null point. Rarely, patients who have congenital nystagmus also have MLN.

## Spasmus Nutans

Spasmus nutans occurs in the first year of life and is a triad of pendular nystagmus, head nodding, and torticollis. The nystagmus often is dissociated (both eyes are not beating together), and in individual patients it can vary from conjugate to disconjugate to monocular over a few minutes. Its direction is primarily horizontal, but it can have vertical and torsional components (Video 9.19.4). In most patients, the syndrome seemingly resolves spontaneously over 1–2 years. However, electronic eye movement recordings show that a small-amplitude, intermittent, dissociated, pendular nystagmus can persist at least until age 5–12 years.<sup>4</sup> Characteristically, the nystagmus frequency is higher (3–11 Hz) and its amplitude more variable than in congenital nystagmus.

Head nodding is found in most patients who have spasmus nutans. It induces vestibulo-ocular responses that transform the nystagmus into larger-amplitude, slower, binocularly symmetrical, pendular oscillations with improved vision. Spasmus nutans must be differentiated from other disorders that cause head nodding and nystagmus, such as vision loss in children, intracranial tumors, and congenital nystagmus. Children with impairment of bilateral vision can have rapid, horizontal, pendular head oscillations; horizontal or vertical nystagmus; and intermittent head tilting during attempts to fixate.<sup>5</sup> The nystagmus can be pendular or jerk, with slow components of constant, increasing, or decreasing velocity.<sup>6</sup> The head shaking seems to be a voluntary, learned adaptation that can improve vision. The diagnostic signs from careful examination of eye and head

**TABLE 9.19.2 Characteristics and Localizations of Vestibular Nystagmus**

Nystagmus	Characteristics	Localization
Spontaneous peripheral vestibular	Jerk, horizontal, small torsional, inhibited by fixation	Labyrinth, eighth nerve (acute)
Central vestibular (fixation) nystagmus	Jerk, pendular, horizontal, vertical, torsional, not inhibited by fixation	Brainstem, cerebellum
Sustained positional vestibular	Jerk, horizontal, small torsional, direction fixed, direction changing (static positioning)	Labyrinth, eighth nerve or brainstem, cerebellum
Benign paroxysmal positional	Jerk, dissociated upbeat, latency, not inhibited by fixation, fatigue (Nylen–Barany maneuver)	Posterior vertical canal
Central paroxysmal positional	Jerk, symmetric, upbeat, downbeat	Brainstem, cerebellum

movements, including electronic recordings, can differentiate spasmus nutans from congenital nystagmus but do not reliably separate spasmus nutans from nystagmus and head nodding due to CNS lesions.<sup>7</sup> Visual loss, optic atrophy, abnormal growth and development, signs and symptoms of CNS disorders, or an older age of onset warrants MRI studies.<sup>8</sup> Some clinicians obtain neuroimaging for all patients who have spasmus nutans. Others do not, because the prevalence of CNS tumors in patients without other signs of CNS masses is low.<sup>9</sup>

## Vestibular Nystagmus

Vestibular nystagmus is the most common type of acquired nystagmus. The characteristics and localizations of several types of vestibular nystagmus are shown in [Table 9.19.2](#).

## Peripheral Vestibular Nystagmus

Peripheral vestibular nystagmus is caused by an acute imbalance of tonic innervation to the brainstem from the vestibular labyrinths and the eighth nerves. Destructive disorders, such as labyrinthitis and vestibular neuritis, decrease innervation from the affected ear and produce jerk nystagmus with slow components toward that ear and fast components beating toward the opposite side. Irritative disorders, such as Meniere's disease, increase innervation from the affected ear and generate jerk nystagmus with fast components toward that ear and slow components toward the opposite ear.

Because the vestibular nerve conveys tonic innervation from a horizontal semicircular canal, a pair of vertical canals, and otoliths (sacculi and utricle), the nystagmus is mainly horizontal but has vertical and torsional components as well (rotary nystagmus). The slow component has a constant velocity waveform. Gaze in the direction of the fast component increases the nystagmus intensity (amplitude  $\times$  frequency), and gaze in the direction of the slow component decreases the intensity (Alexander's law). Nausea and vertigo with the sensation of rotation of the environment or self-rotation in the direction of the fast component are usually present. Tinnitus, hearing loss, and ear pain also may be present. The nystagmus intensity is high during the first few days but decreases spontaneously. At this time, fixation might inhibit the nystagmus. However, blocking fixation reveals the nystagmus. Imbalance of tonic inputs from the otoliths can cause a transient skew deviation (hypotropic eye ipsilateral to the damaged ear).

## Central Vestibular Nystagmus

Lesions of the vestibular nuclei, the cerebellum, or the connections between the flocculonodular lobes and the brainstem can cause central vestibular nystagmus. In contrast to peripheral vestibular nystagmus, fixation does not greatly inhibit the nystagmus, which leads to the synonymous term *fixation nystagmus*. Central vestibular nystagmus can be purely horizontal, torsional, or vertical because horizontal and vertical vestibulo-ocular pathways begin to separate in the vestibular nuclei. Jerk nystagmus in primary gaze that is predominantly torsional is associated with lesions of the vestibular nuclei on the side contralateral to the fast component.<sup>10</sup>

## Positional Vestibular Nystagmus

Positional vestibular nystagmus is not present in the sitting upright position but is induced by the supine and lateral positions or by rapid

**TABLE 9.19.3 Characteristics and Localizations of Gaze-Evoked Nystagmus**

Nystagmus	Characteristics	Localization
Physiological, endpoint	Jerk, small-amplitude, intermittent, extremes of horizontal and up gaze	Physiological
Gaze-paretic (symmetric)	Jerk (decreasing velocity slow components) at 30° eccentric gaze	Nonlocalizing (drugs, mental fatigue)
Gaze-paretic (asymmetric)	Jerk (decreasing velocity slow components), horizontal, at 30° eccentric gaze, larger amplitude toward side of lesion	Lesions of brainstem, cerebellum, cerebral hemisphere
Rebound	Jerk, horizontal, decreases and direction can reverse in eccentric gaze, transient jerk nystagmus on return to primary gaze, fast components beating toward eccentric gaze	Cerebellum
Myasthenia gravis	Jerk, horizontal or vertical, gradual onset in prolonged eccentric gaze	Myoneural junction (fatigue—increasing transmission block)

movements of the head and body into head-hanging positions. Fixation suppresses the nystagmus when the cause is a peripheral vestibular lesion but does not suppress it when a central vestibular lesion is present. The nystagmus direction can remain the same in the right and left lateral positions (direction fixated), or it can change (direction changing). The fast components may beat toward the down ear (geotropic) or toward the up ear (apogeotropic). Both peripheral and central vestibular lesions can cause direction fixated and direction changing positional nystagmus.

## Benign Paroxysmal Positional Nystagmus

Rapid positioning of the head and body into the right or left head-hanging position (Nylen–Barany or Dix–Hallpike maneuver) induces benign paroxysmal positional nystagmus (BPPN). After a delay of 1–2 seconds, an intense vertical nystagmus develops. Fixation does not suppress the nystagmus, and the patient usually complains of vertigo after the maneuver. Characteristic binocular asymmetry exists in which the nystagmus primarily beats up in the higher eye (i.e., the eye opposite to the head-hanging position) and is oblique and torsional in the lower eye. The asymmetry is explained by the primary and secondary actions of the vertical extraocular muscles stimulated by the posterior semicircular canals (contralateral inferior rectus and ipsilateral superior oblique muscles). The nystagmus dies away over several seconds. Repetition of the maneuver soon after the initial positioning generates a less intense nystagmus (fatigue).

The cause of BPPN is otoconia that have become dislodged from the otoliths (utricle macula) and either are attached to the cupula of a posterior semicircular canal (cupulolithiasis) or freely move in that canal (canalolithiasis). Endolymph flow in the posterior canal produces an abnormally prolonged deflection of the hair cells in the crista of the canal. Positional exercises, such as Epley's maneuver, can move the granules back into the utricle and eliminate the positional nystagmus and vertigo.<sup>11</sup> Canalolithiasis and paroxysmal positional nystagmus of the horizontal and anterior posterior canals can occur spontaneously or can be produced by repositioning for the posterior canal form of BPPN.<sup>12</sup> The Nylen–Barany maneuver can induce paroxysmal positional nystagmus other than BPPN, such as downbeat nystagmus and other types of central vestibular nystagmus.<sup>13</sup> Therefore, the typical features of BPPN must be present for the diagnosis to be confirmed; it can result from viral labyrinthitis, head injury, and infarction of the inner ear. Most often it is an isolated disorder in older adults.

## Gaze-Evoked Nystagmus

Several types of gaze-evoked nystagmus are present in eccentric gaze but not in primary gaze ([Table 9.19.3](#)). In gaze-paretic nystagmus, no nystagmus occurs in primary gaze, but a jerk nystagmus occurs in about 30° of eccentric gaze. The slow components move the eyes toward primary gaze and have waveforms with exponentially decreasing velocities (see [Fig. 9.19.1](#)). Fast components beat toward the intended eccentric gaze position. The drift toward primary gaze results from impairment of gaze-holding mechanisms that involve the nucleus prepositus hypoglossi and medial vestibular nucleus (the “neural integrator”) and their connections with the flocculonodular lobe of the cerebellum. The eye position signal cannot hold the eyes eccentrically in the orbits, so they drift back toward primary gaze.

Normal, physiological, endpoint nystagmus is present in the extremes of horizontal and upward gazes of about 45°–50°. Therefore, nystagmus at

only 30° is likely to be a pathological finding. Endpoint nystagmus is irregular and might be slightly dissociated (larger amplitude in the abducting eye), which mimics the dissociated nystagmus associated with internuclear ophthalmoplegia. However, the other eye movement abnormalities associated with internuclear ophthalmoplegia are absent. Generally, physiological endgaze nystagmus dampens within 6 seconds.

Symmetrical gaze-paretic nystagmus, in which the nystagmus intensity is the same in right gaze and left gaze, usually is not a localizing sign. It is produced by mental fatigue; CNS depression caused by barbiturates, tranquilizers, anticonvulsants, alcohol, and other drugs; and disorders of the cerebral hemispheres, brainstem, and cerebellum. Asymmetrical, horizontal, gaze-paretic nystagmus often is lateralizing. A lesion of the brainstem or cerebellum is generally on the side of greater nystagmus intensity.

Myasthenia gravis can produce a horizontal or upbeat gaze-paretic nystagmus. Initially, little or no nystagmus exists, but as the extraocular muscles fatigue, nystagmus develops. In horizontal gaze, the amplitude of the fast component in the abducting eye is often larger than that in the adducting eye as a result of the greater fatigue of the medial rectus muscle. Normal subjects can have an endpoint nystagmus of very small amplitude that increases with fatigue.

## Rebound Nystagmus

Rebound nystagmus is a type of horizontal, gaze-paretic nystagmus in which the jerk nystagmus gradually decreases in amplitude as the eyes remain in eccentric gaze for many seconds. In some instances, the nystagmus direction actually reverses (centripetal nystagmus); for example, it becomes left beating in right gaze. On return to primary gaze, a jerk nystagmus occurs that beats in the direction opposite to that of the previous gaze-paretic nystagmus. The secondary nystagmus decreases and disappears after several seconds. Rebound nystagmus usually is associated with disorders of the cerebellum. Vertical rebound nystagmus occurs less often. Normal individuals can experience a few beats of rebound nystagmus after prolonged eccentric gaze if no fixation target is present on return to primary gaze (lights turned off).

## Alternating Nystagmus

The direction of jerk nystagmus changes spontaneously in alternating nystagmus (Table 9.19.4). In periodic alternating nystagmus (PAN), a repetitive cycling of right-beating and left-beating nystagmus occurs in primary gaze. The amplitude of nystagmus gradually increases and decreases over a period of about 90 seconds, followed by a short period of about 10 seconds in which there is no nystagmus, small-amplitude vertical or torsional nystagmus, or square-wave jerks (null period). Nystagmus that beats in the opposite direction then ensues, increasing and decreasing over 90 seconds, and is followed by a null period. The cycle continues and is not affected by other eye movements, except for strong rotational vestibular stimuli, which can reset the cycle. During periods of jerk nystagmus, patients have horizontal oscillopsia and blurred vision. They might spontaneously turn their heads in the direction of the fast component. This moves the eyes to a position of minimal nystagmus and better vision (null position). The null position moves gradually to the right, back to primary gaze, to the left, and back to primary gaze. This type of alternating nystagmus is almost always associated with cerebellar disorders. Ablation of the nodulus and uvula was shown to produce periodic alternating nystagmus in monkeys.<sup>60</sup>

Alternating nystagmus also occurs in congenital nystagmus, in MLN, and in association with severe binocular visual loss from many causes (e.g.,

chronic papilledema, vitreous hemorrhage, cataract). In congenital nystagmus and MLN, the change in nystagmus direction can be caused by a shift of fixation from one eye to the other. However, congenital nystagmus and periodic alternating nystagmus can coexist, for example, in patients with albinism.<sup>14</sup> The periods of alternating nystagmus are not as symmetrical or regular as those in periodic alternating nystagmus associated with cerebellar disorders, although shifting of the null positions also occurs.

## Upbeat Nystagmus

Upbeat nystagmus in primary gaze is caused by lesions that affect the brainstem, especially the lower pontine tegmentum (see Table 9.19.4).<sup>15</sup> Lesions of the medulla, midbrain, thalamus, and cerebellum also can cause upbeat nystagmus. Common causes of these lesions are multiple sclerosis, infarction, intra-axial tumor, Wernicke's encephalopathy, brainstem encephalitis, and cerebellar degeneration. Rarely, upbeat nystagmus can be a form of congenital nystagmus and might be seen as a transient finding in normal infants. Upbeat nystagmus that is present only in upgaze and is associated with symmetrical, horizontal, gaze-paretic nystagmus is usually a type of gaze-paretic nystagmus that might not have a localizing significance. Patients with upbeat nystagmus may have slow components with constant velocity, decreasing velocity, or increasing velocity waveforms. Nicotine can produce a small-amplitude upbeat nystagmus in the dark in normal subjects.

## Downbeat Nystagmus

Downbeat nystagmus in primary gaze usually is caused by a structural lesion in the posterior fossa at the level of the craniocervical junction (see Table 9.19.4). The nystagmus intensity characteristically increases in horizontal eccentric gaze and may be increased by convergence. Convergence also can convert an upbeat nystagmus in primary gaze to a downbeat nystagmus. Lesions of the cerebellum and pons are associated most often with downbeat nystagmus, and the most common causes are infarction, cerebellar degeneration, multiple sclerosis, and congenital malformations.<sup>16</sup> Downbeat nystagmus may be part of an acquired syndrome in adulthood consisting of cerebellar ataxia, lower brainstem dysfunction, or cranial nerve palsies caused by Arnold–Chiari malformations (types 1 and 2). Although such malformations are not the most common cause of downbeat nystagmus, MRI of the posterior fossa should be performed because surgical decompression can diminish the nystagmus and the other abnormalities in the syndrome. Rarely, a variety of other disorders can cause downbeat nystagmus, including lithium toxicity, magnesium deficiency, vitamin B<sub>12</sub> deficiency, midbrain infarction, brainstem encephalitis, Wernicke's encephalopathy, increased intracranial pressure with hydrocephalus, syringobulbia, cerebellar tumor, and anticonvulsant medication. Downbeat nystagmus has been reported to occur as an inherited congenital disorder. The slow components can have constant velocity, increasing velocity, and decreasing velocity waveforms.

## Dissociated Nystagmus

In several types of dissociated nystagmus, eye movements are strikingly disconjugate (Table 9.19.5). Nystagmus might be present in only one eye (spasmus nutans, optic glioma, and uniocular visual loss), larger in one

**TABLE 9.19.4 Characteristics and Localizations of Other Types of Fixation Nystagmus**

Nystagmus	Characteristics	Localization
Periodic alternating	Jerk, horizontal, in primary position, regular phases of right-beating, null, left-beating (shifting null position)	Cerebellar nodulus and uvula
Alternating (irregular)	Jerk, horizontal, in primary position, variable, asymmetric phases	Congenital nystagmus, severe, binocular visual loss
Upbeat	Jerk, fast components beat upward	Only in upgaze—part of symmetric gaze—paretic nystagmus; in primary gaze—lower pons
Downbeat	Jerk, fast components beat downward, vertical intensity increases in horizontal gaze	Cerebellum, lower brainstem

**TABLE 9.19.5 Characteristics and Localizations of Dissociated Nystagmus**

Nystagmus	Characteristics	Localization
Acquired pendular in adults	Pendular, horizontal, vertical, torsional, disconjugate (coexisting palatal myoclonus)	Brainstem, cerebellum
Superior oblique myokymia	Pendular, jerk, torsional, vertical, high-frequency, small-amplitude, monocular	Trochlear nucleus
See-saw	Pendular, vertical, torsional, rising eye intorts, falling eye extorts; rarely jerk	Midbrain (interstitial nucleus of Cajal)
Abducting “nystagmus” of internuclear ophthalmoplegia	Jerk, horizontal, decreasing velocity slow components, larger in abducting eye in horizontal gaze	Medial longitudinal fasciculus in pons, midbrain
Abducting nystagmus of myasthenia gravis	Gaze-paretic nystagmus in horizontal gaze, greater paresis of medial rectus muscle	Myoneural junction—myasthenia gravis

eye than in the other (abduction nystagmus in internuclear ophthalmoplegia), or present in different directions (see-saw nystagmus). Dissociated nystagmus present in the primary position is often pendular and is often jerk nystagmus in eccentric gaze.

### Acquired Pendular Nystagmus in Adults

Acquired pendular nystagmus usually has horizontal, vertical, and torsional components and is often disconjugate. Lesions of the pons, medulla, midbrain, and cerebellum, often caused by multiple sclerosis or infarction, produce oscillations with a typical frequency of 3–4 Hz. MRI studies show large or multiple lesions, which suggests that more than one pathway must be damaged to produce pendular nystagmus.<sup>17</sup> Head tremor may be present. The nystagmus trajectory also can be elliptical or circular. When acquired pendular nystagmus is associated with similar movements of the soft palate, tongue, facial muscles, pharynx, and larynx, it is called *ocular-palatal myoclonus*. The cause usually is an infarction that affects the structures of Mollaret's triangle and their connections (red nucleus in the midbrain, inferior olive in the medulla, and contralateral dentate nucleus of the cerebellum). Hypertrophy of the inferior olive and the pendular oscillations begin several months later. Extensive hemorrhage in the pons can produce a large-amplitude, vertical, pendular nystagmus and bilateral horizontal gaze palsies.

### Monocular Visual Loss and Bilateral Visual Loss

Children who have monocular visual loss from causes other than optic nerve glioma may have monocular, high-frequency, small-amplitude, pendular nystagmus.<sup>18</sup> They do not have intracranial tumors, spasmus nutans, or signs of damage to the optic nerve or optic chiasm. The nystagmus can disappear after successful treatment for the monocular visual loss. Adults who have acquired, severe monocular visual loss (e.g., dense cataract) may have very low-frequency, irregular, vertical drift and jerk nystagmus (Heimann-Bielschowsky phenomenon), which can also be abolished with recovery of vision. Bilateral blindness results from a number of causes and can produce large-amplitude oscillations with small-amplitude ones superimposed. Both oscillations are horizontal and vertical and can have jerk and pendular waveforms. The direction of the jerk nystagmus varies over time (shifting null position). Vestibulo-ocular responses are impaired; volitional saccades and the fast components of vestibular nystagmus may be absent. Head nodding is usually present. Children who have congenital stationary night blindness and rod monochromatism may have small-amplitude, high-frequency, disconjugate, pendular nystagmus, similar to that seen in spasmus nutans.

### See-Saw Nystagmus

See-saw nystagmus is a disconjugate, vertical, pendular nystagmus. In one half of a cycle, the rising eye also intorts and the falling eye extorts. The movements are reversed in the other half cycle. See-saw nystagmus is caused most often by large parasellar tumors that cause bitemporal hemianopsia (optic chiasm) and impinge on the third ventricle. Less often, head trauma and infarction of the upper brainstem are the causes. Congenital forms occur, including those in infants who have albinism. In the congenital forms, the rising eye extorts and the falling eye intorts. See-saw nystagmus may be caused by damage to otolithic pathways involving the interstitial nucleus of Cajal, which participate in the ocular tilt reaction. Stereotactic ablation of the interstitial nucleus of Cajal, clonazepam, and baclofen abolish the nystagmus. Rarely, see-saw nystagmus has a jerk waveform, in which case it arises from a unilateral midbrain lesion. The lesion hypothetically damages the interstitial nucleus of Cajal (torsional eye velocity generator) and spares the adjacent rostral interstitial nucleus of the medial longitudinal fasciculus (MLF; torsional fast component generator).<sup>19</sup>

### Abducting Nystagmus in Internuclear Ophthalmoplegia

In internuclear ophthalmoplegia, horizontal gaze in the direction opposite to the lesion in the MLF in the midbrain or pons induces a jerk nystagmus in the abducting eye and a smaller (or no) nystagmus in the paretic, adducting eye (Video 9.19.5). This abducting nystagmus is the most common type of dissociated nystagmus. It might be simply a gaze-paretic nystagmus with superimposed paresis of the medial rectus muscle ipsilateral to the MLF lesion. However, in many patients, the speed of the exponentially velocity-decreasing waveform of the centripetal slow component is much higher than that found in gaze-paretic nystagmus. The abducting saccade has a characteristic overshooting waveform with a rapid, postsaccadic drift. The hypermetria may be a consequence of an adaptive increase in innervation in response to the weakness of adduction. The saccadic pulse is

increased, but the step is not increased proportionately (pulse-step mismatch) or is absent, which results in a rapid centripetal drift. Therefore, the abducting nystagmus may be caused by a train of hypermetric saccades.<sup>20</sup> Physiological endpoint nystagmus also can be dissociated slightly (larger amplitude in the abducting eye), but the other ocular motor abnormalities that are characteristic of internuclear ophthalmoplegia are absent. These abnormalities consist of limitation of adduction, slow adducting saccades, hypermetric abducting saccades, upbeat nystagmus, and skew deviation.

### Ocular Bobbing

Stupor and coma are associated with several ocular abnormalities, including ocular bobbing. Intermittent, irregular, conjugate, downward saccades are followed by slower, upward drift movements. Patients who have ocular bobbing have extensive damage to the pons from hemorrhage or compression or have toxic or metabolic encephalopathies. Several variants of ocular bobbing exist. In inverse bobbing, or ocular dipping, downward, slow movements are followed by upward saccades and then back toward the primary position. In converse bobbing, or reverse ocular dipping, large-amplitude, upward saccades are followed by downward drifts.

### Saccadic Intrusions

Reflex saccades to objects that enter the visual field are mediated through pathways from the visual association areas of the parietal lobes and temporal lobes and from ocular motor fields in the frontal lobes. They project to the superior colliculi and the saccade-related areas of the brainstem. Normally, reflex saccades to these sites can be inhibited voluntarily. Pathways from the frontal lobes to the basal ganglia (pars reticularis of the substantia nigra) and superior colliculus may be important for the inhibition of reflex saccades. Patients who suffer frontal lobe diseases, including Alzheimer's disease, Huntington's disease, progressive supranuclear palsy, and schizophrenia, have inappropriate saccades that interrupt fixation. These saccadic intrusions have been called the "visual grasp reflex" (see Fig. 9.19.2; Table 9.19.6). Saccadic intrusions do not represent true nystagmus as these disorders do not exhibit a slow phase.

### Superior Oblique Myokymia

Superior oblique myokymia is a very high-frequency, torsional, and oblique oscillation of one eye that causes monocular oscillopsia and, occasionally, vertical diplopia. Careful observation of the conjunctival blood vessels at the slit lamp or of the fundus with an ophthalmoscope reveals the extremely high-frequency, low-amplitude, pendular oscillations, as well as the occasional jerky nystagmoid movements as well as tonic intorsion and infraduction that produce diplopia. Electromyography of the superior oblique muscle has shown abnormal discharges at a frequency of 35 Hz. Superior oblique myokymia usually occurs in otherwise healthy adults, can remit spontaneously, and may recur. Rarely, it is associated with brainstem disorders, such as multiple sclerosis or a pontine tumor.

**TABLE 9.19.6 Characteristics and Localizations of Saccadic Intrusions and Oscillations**

Type	Characteristics	Localization
Square-wave jerks	Horizontal, 1–5°, 200 ms intersaccadic intervals	Not localizing
Macrosquare-wave jerks	Horizontal, 10–40°, 100 ms intersaccadic intervals	Cerebellum
Macrosaccadic oscillations	Horizontal saccadic dysmetria, series of hypermetric saccades, 200 ms intersaccadic intervals	Cerebellum
Voluntary "nystagmus"	Horizontal, high-frequency, low-amplitude, intermittent, no intersaccadic intervals	Volitional
Saccadic pulses	Horizontal, single or double saccades with no steps	Cerebellum, lower brainstem
Ocular flutter	Horizontal, large-amplitude, linear and curvilinear trajectories, no intersaccadic intervals	Cerebellum, lower brainstem
Opsoclonus	Multidirectional, large-amplitude, linear and curvilinear trajectories, no intersaccadic intervals	Cerebellum, lower brainstem
ms, millisecond.		

See clip:  
9.19.5

## Convergence–Retraction Nystagmus and Convergence Nystagmus

Voluntary or reflex upward saccades in Parinaud's syndrome (dorsal mid-brain syndrome) are hypometric and show simultaneous adduction and retraction of both eyes. Simultaneous contraction of antagonist muscles causes the retraction. Optokinetic stimuli that move downward elicit upward, reflex saccades and the pattern of convergence–retraction nystagmus (Video 9.19.6). Convergence nystagmus has been shown to be caused by an Arnold–Chiari malformation type 1, which resolved with surgical decompression of the foramen magnum.<sup>21</sup> It can also be caused by Whipple's disease, which produces contractions of the masticatory muscles (ocular masticatory myorhythmia) and a vertical gaze palsy.<sup>22</sup> Antibiotics can resolve the oculofacial–skeletal myorhythmia.

See clip:  
9.19.6

### Square-Wave Jerks

Normal subjects have infrequent, small-amplitude ( $<1^\circ$  to a few degrees), horizontal saccades that move the eyes away from the fixation target and then back to the target, called *square-wave jerks* (see Fig. 9.19.2). Pause occurs between the to-and-fro saccades (intersaccadic interval) of about 200 milliseconds, and this allows sufficient foveation time for normal visual acuity with no oscillopsia. The frequency of square-wave jerks increases in the dark. Larger ( $1^\circ$ – $5^\circ$ ) and more frequent ( $>2$  Hz) square-wave jerks are abnormal and are associated with cerebellar disorders, progressive supranuclear palsy, Parkinson's disease, Huntington's disease, and schizophrenia. They occur sporadically or in bursts.

### Macrosquare-Wave Jerks

Macrosquare-wave jerks are horizontal and large ( $10^\circ$ – $40^\circ$ ) and have intersaccadic intervals of about 100 milliseconds. They are found in cerebellar disorders (e.g., multiple sclerosis and olivopontocerebellar atrophy) and occur sporadically or in bursts.

### Macrosaccadic Oscillations

Macrosaccadic oscillations are a type of saccadic dysmetria. A hypermetric saccade overshoots the target and is followed by a series of hypermetric, corrective saccades that straddle the target and gradually decrease in size until the target is fixated. The intersaccadic intervals are 200 milliseconds long. Macrosaccadic oscillations are associated with cerebellar disorders.

### Voluntary “Nystagmus”

Normal subjects can voluntarily produce bursts of high-frequency (10–20 Hz), small-amplitude (a few degrees), horizontal, saccadic oscillations, called voluntary “nystagmus.” This is not a true nystagmus because it consists of to-and-fro, back-to-back saccades. Because no intersaccadic intervals occur, visual acuity is poor, and oscillopsia is present during the oscillations. Voluntary “nystagmus” cannot be sustained for more than several seconds; subjects show signs of intense effort, such as squinting, facial muscle contractions, and convergence.

### Saccadic Pulses

Saccadic pulses are saccadic intrusions in which saccades move the eyes away from the fixation target, followed by a rapid drift back to the target (glissade). They represent saccadic pulses without steps; they can occur singly, in a series, or in a train (saccadic pulse train) that mimics nystagmus (abducting nystagmus of internuclear ophthalmoplegia). Saccadic pulses occur in normal subjects, patients who have myoclonus, and patients who have multiple sclerosis. Double saccadic pulses are pairs of saccadic pulses that move in opposing directions and occur back-to-back with no intersaccadic intervals. They are part of a continuum of other saccadic oscillations with no intersaccadic intervals (ocular flutter and opsoclonus).

### Ocular Flutter

Ocular flutter consists of bursts of moderately large-amplitude, horizontal, back-to-back saccades without intersaccadic intervals. Blurred vision and oscillopsia usually are present. Ocular flutter can occur in the primary position and after a refixation saccade (flutter dysmetria); it is associated with the same disorders of the brainstem and cerebellum that produce opsoclonus (see next section). Eyelid blinks induce bursts of large-amplitude flutter in neurodegenerative disorders and a few beats of low-amplitude flutter in normal subjects.

### Opsoclonus

In opsoclonus, a series of large-amplitude, back-to-back, multidirectional saccades interrupt fixation. The directions of the to-and-fro saccades can

be horizontal, vertical, or oblique; their trajectories can be linear or curvilinear, and the frequency is high (10–15 Hz). The chaotic appearance of the oscillations has led to the use of the term “saccadomania.” In its severe form, opsoclonus is nearly continuous and persists even in some stages of sleep. With improvement, or in its milder form, the oscillations are intermittent. During fixation, saccadic burst cells in the pontine paramedian reticular formation (horizontal saccades) and in the rostral interstitial nucleus of the MLF (vertical saccades) are inhibited by tonic activity in pause cells in the nucleus raphe interpositus in the midbrain. Pause cell activity is momentarily inhibited during saccades, and this allows the burst cells to fire and generate the saccadic pulse signal. An abnormal decrease in pause cell activity as a result of direct damage to these cells or abnormal input to them from other neurons might produce opsoclonus and ocular flutter.

Opsoclonus often is associated with cerebellar ataxia and limb myoclonus. The disorders that cause opsoclonus damage the brainstem or cerebellum; they include benign brainstem encephalitis in children and adults following viral illnesses, myoclonic encephalopathy of infants (dancing eyes and dancing feet), paraneoplastic brainstem and cerebellar syndromes in children (neuroblastoma) and adults (small cell lung carcinoma, breast carcinoma, ovarian tumors), and multiple sclerosis.<sup>23,24</sup> Opsoclonus and ocular flutter have been reported in association with drug toxicities, exposure to toxic chemicals, and hyperosmolar coma and as transient findings in normal neonates. Adrenocorticotrophic hormone can diminish the saccadic oscillations of infantile myoclonic encephalopathy and neuroblastoma, and corticosteroids can be effective in paraneoplastic syndromes in adults. Some normal subjects can produce saccadic oscillations volitionally, including many of the characteristics of opsoclonus and ocular flutter.<sup>25</sup>

## TREATMENT

### Drug Treatment

The goal of treating vestibular nystagmus is mainly to diminish the associated vertigo. The large number of medications that are used is an indication that no optimal drug therapy exists for most patients. The classes of drugs include anticholinergics (scopolamine [hyoscine]), antihistamines (meclizine), monoaminergics (ephedrine), benzodiazepines (diazepam), phenothiazines (prochlorperazine), and butyrophenones (droperidol). Unfortunately, drowsiness from many of these drugs limits their efficacy for chronic, recurrent vertigo. An exception is acetazolamide, which is very effective for the treatment of familial periodic ataxia with nystagmus.<sup>26</sup>

The goal in the treatment of nonvestibular forms of nystagmus and saccadic oscillations is to improve vision by alleviating the associated blurring and oscillopsia. As in vestibular nystagmus, many medications have been tried, but few have been found to be consistently effective.<sup>27</sup> Only a few double-blind studies have been carried out: anticholinergics for acquired pendular nystagmus,<sup>28</sup> muscarinic antagonists for acquired pendular and downbeat nystagmus,<sup>29</sup> and 4-aminopyridine for downbeat nystagmus.<sup>30</sup>

Baclofen is an analogue of gamma-aminobutyric acid (GABA) and was developed to treat skeletal muscle spasm. It consistently decreases the symptoms and signs of periodic alternating nystagmus.<sup>31</sup> To diminish drowsiness, the initial dosage is low, 5 mg by mouth three times a day, and is increased gradually. Patients perceive a return of symptoms after a few hours. Baclofen decreases the slow component velocity and oscillopsia in some patients who have upbeat and downbeat nystagmus.<sup>32</sup> Its therapeutic effect might result from augmentation of the physiological inhibitory effect of GABA on the vestibular nuclei in the vestibulocerebellum and on the velocity storage mechanism.

4-Aminopyridine is an inhibitor of voltage-gated potassium channels and improves conduction in demyelinated nerve fibers, leading to benefits in lower extremity strength and walking speed in patients with multiple sclerosis.<sup>33</sup> A randomized, double-blind trial demonstrated that 57% of patients with downbeat nystagmus (idiopathic or related to cerebellar degeneration) treated with 4-aminopyridine experienced improved nystagmus waveform.<sup>30</sup> Near visual acuity and locomotor parameters also improved. The dosages used were 5 and 10 mg by mouth, four times daily.

Clonazepam is an antiepileptic agent that has been shown to decrease downbeat nystagmus in some patients.<sup>34</sup> Its most common side effect is drowsiness. The initial dosage of 0.5 mg by mouth three times a day is increased gradually. Gabapentin (900–1500 mg/day) has been shown to decrease, but not abolish, acquired pendular nystagmus in a few patients.<sup>35</sup> Topical and systemic carbonic anhydrase inhibitors (e.g., brinzolamide) have been found to improve nystagmus waveform and visual acuity in small studies of patients with congenital nystagmus.<sup>36–38</sup>

Adrenocorticotrophic hormone can diminish ocular flutter and opsoclonus in infantile myoclonic encephalopathy and neuroblastoma. Corticosteroids can decrease these saccadic oscillations in paraneoplastic, cerebellar ataxia syndromes in adults. Carbamazepine, baclofen, clonazepam, gabapentin, propranolol, and topical timolol have been used to treat superior oblique myokymia; carbamazepine is generally considered the most effective but has more potential side effects.<sup>39,40</sup>

## Optical Treatment

In congenital nystagmus, convergence and eccentric gaze often decrease the nystagmus and improve vision. To induce convergence, 7 prism diopters (PD) of base-out prism can be placed in each spectacle lens. If the patient is young, -1.00 D can be added to the spherical correction. If the null zone is in horizontal eccentric gaze, the spectacle prism powers can be modified to incorporate a prism effect in which the eyes conjugately rotate toward the null zone (prism apices toward the null zone). Contact lenses have fewer optical aberrations and usually correct the refractive errors in patients who have congenital nystagmus more effectively compared with spectacles. In addition, tactile sensory feedback from the contact lenses might diminish the nystagmus intensity. One congenital nystagmus patient reported transient oscillopsia when contact lenses were removed after a short therapeutic trial.<sup>41</sup>

The combination of a high plus spectacle lens and a high minus contact lens for one eye has been devised to stabilize retinal images in that eye and improve vision.<sup>42</sup> This combination places the image at the eye's center of rotation. However, because vestibulo-ocular eye movements and volitional eye movements do not cause retinal image movement with these lenses, walking is difficult.

In patients who have MLN, spectacle treatment for an accommodative component of their esotropia can transform MLN to latent nystagmus or decrease MLN, each of which leads to an improvement of binocular visual acuity.<sup>43</sup>

## Surgical Treatment

An eccentric null zone in congenital nystagmus often produces a habitual face turn. The face turn, if marked, can cause difficulties when viewing at distance or reading; in addition, it can be a cosmetic and psychosocial problem. Resections and recessions of the four horizontal rectus muscles can move the null zone toward the primary position (Anderson-Kestenbaum procedure), which improves vision in the primary position.<sup>44,45</sup> However, months after the surgery, the null zone may become eccentric again. If convergence decreases congenital nystagmus significantly, surgery to induce a greater convergence effort can be combined with the Anderson-Kestenbaum procedure.<sup>46</sup> Surgical procedures to decrease nystagmus intensity in patients without face turn include retroequatorial recession, myectomy without reattachment, anterior extirpation, and tenotomy with reattachment of all four horizontal rectus muscles.<sup>47-49</sup> Extirpation

and myectomy may induce postoperative strabismus and limitation of ductions.<sup>47</sup> Chin-up or chin-down head positioning may be addressed with vertical rectus muscle resection and/or recession, or oblique muscle surgery.<sup>50</sup> Surgical options for head tilt include transposition of horizontal or vertical rectus muscles, or oblique muscle surgery.<sup>51-53</sup>

In patients who have strabismus and MLN, strabismus surgery can change the MLN to latent nystagmus and improve binocular visual acuity.<sup>43</sup> In Arnold-Chiari malformations, suboccipital decompression can diminish downbeat nystagmus if permanent damage to the midline cerebellum and lower brainstem has not occurred. Procedures to weaken the superior oblique and ipsilateral inferior oblique muscles have been used to treat superior oblique myokymia.

## Other Treatments

A variety of other therapies have been used to treat nystagmus. Of these, Epley's maneuver for BPPN is, by far, the most effective.<sup>11</sup> Tactile stimulation of the face and neck,<sup>54</sup> auditory biofeedback, and acupuncture have been shown by electronic recordings to decrease congenital nystagmus. However, their efficacy outside of the laboratory setting has not been established. Retrobulbar injections or intramuscular injections of botulinum A toxin decrease nystagmus by paralyzing the extraocular muscles. They have been used to treat congenital nystagmus,<sup>55</sup> latent nystagmus,<sup>56</sup> and acquired nystagmus.<sup>57</sup> The paralysis is temporary, requiring repetition of the injection every few months. The side effects are diplopia, ptosis, filamentary keratitis, and increased nystagmus in the noninjected eye from plastic-adaptive changes in response to the paresis of the injected eye.<sup>58,59</sup>

# Pupillary Signs of Neuro-Ophthalmic Disease

9.20

John J. Chen, Randy H. Kardon

## Definitions:

- **Afferent pupillary disorders** result from interference with light input to the pupillomotor system by dense media opacities or severe deficits in any of the retinal layers, in the optic nerve, chiasm, optic tract, or midbrain pretectal area resulting in a symmetrical decrease in the contraction of both pupils in response to light given to the affected eye.
- **Efferent pupillary disorders** result from damage to the pretectal interneuron or Edinger–Westphal nucleus in the midbrain, in the parasympathetic or sympathetic peripheral nerve that supplies the iris muscles, or in the iris muscles themselves, leading to asymmetrical pupils (anisocoria).

## Key Features

- Relative afferent pupillary defects cause less pupil contraction when one eye is stimulated by light than when the opposite eye is stimulated by light.
- Efferent pupillary defects cause anisocoria, a difference in pupil size between the right and left eyes, the extent of which depends on the condition of lighting or near effort.

## Associated Features

- Relative afferent pupillary defects are typically associated with visual field or electroretinographic asymmetries between the two eyes. Asymmetrical differences in retinal appearance, optic nerve appearance or thickness of the inner or outer retinal layers (as observed by optical coherence tomography) may occur in association with a relative afferent pupillary defect.
- Efferent pupillary defects may be associated with either damage to the parasympathetic or sympathetic nerves that supply the iris or direct damage to the iris sphincter or dilator muscles that results in immobility of the pupil.

## INTRODUCTION

In this chapter, the pupillary appearance and response to light stimulus is discussed from a practical, clinical standpoint. The focus is on features of pupil examination that enable accurate diagnosis and management of diseases of the afferent visual system and those that affect pupil size. The chapter is divided into two parts:

- Pupil examination to assess afferent visual input.
- The diagnostic implications of abnormal integration of the efferent output to the pupils.

Abnormal integration may result in pupils of unequal diameter (anisocoria), pupils that do not dilate well in darkness, or a light–near dissociation, in which pupil contraction to a near reflex greatly exceeds the pupil constriction to a light reflex.

## RELATIVE AFFERENT PUPILLARY DEFECTS

In general, the most important clinical use of the pupil is in the assessment of afferent input from the retina, optic nerve, and subsequent anterior visual pathways (chiasm, optic tract, and midbrain pathways). Because the pupillary light reflex represents the sum of the entire neuronal input (photoreceptors, bipolar cells, ganglion cells, and axons of ganglion cells),

**Fig. 9.20.1 Demonstration of a Large Afferent Defect in the Right Eye.** This is best demonstrated when the light is alternated from eye to eye at a steady rate. The light is kept just below the visual axis and 1–2 inches (3–5 cm) from each eye. Each eye is illuminated for about 2 seconds and then the light switched quickly to the other eye; this allows comparison of the initial direct pupil contraction with light in each eye.

damage anywhere along this portion of the visual pathway reduces the amplitude of pupil movement in response to a light stimulus.<sup>1,2</sup> Thus, the clinician can establish any asymmetrical damage between the two eyes by a simple comparison of how well the pupil contracts to a standard light shone into one eye compared with the same light shone into the other eye.<sup>3</sup> Observation of pupil movement in response to alternating the light back and forth between the two eyes is the basis for the alternating light test, or “swinging flashlight” test, used to assess the relative afferent pupillary defect (rAPD) (Fig. 9.20.1).<sup>4,5</sup> For the swinging flashlight test, each eye is illuminated for 2–3 seconds then the illumination is quickly switched to the other eye to compare the initial direct pupil contraction (velocity and amplitude) and any pupillary dilation/escape.

The pupillary light reflex summates the entire area of the visual field, with some increased weight given to the central 10°.<sup>2</sup> Thus, in general terms, the pupillary light reflex is roughly proportional to the amount of working visual field. Damage to peripheral portions of the retina and visual field defects outside the central field also reduce the amplitude of the pupillary light reflex, and therefore it is not uncommon to have an afferent pupillary defect with normal visual acuity, such as an inferior altitudinal visual field defect from nonarteritic anterior ischemic optic neuropathy that spares the central vision. The rAPD is proportional to the visual field loss and not the visual acuity.

The pupillary light reflex is one of the few objective reflexes that can be used as a clinical test for the detection and quantification of abnormalities of the retina, optic nerve, optic chiasm, or optic tract. Because the amount of the rAPD is correlated, to a large extent, with the amount of asymmetry of visual field deficit between the two eyes, it may be used to help substantiate abnormal results of perimetric testing<sup>6–9</sup>; this often helps the clinician

TABLE 9.20.1 Common Diseases That Produce Relative Afferent Pupillary Defects

Condition	Site	Log Unit Relative Afferent Pupillary Defect	Influencing Factors
Intraocular hemorrhage	Anterior chamber or vitreous	0.0–0.9	Density of hemorrhage
Diffusing media opacity	Cataract or corneal scar	0.0–0.3 in opposite eye	Dispersion of light produces increase in light input
Refractive error	Ocular	0.0	Anisometropic amblyopia may cause a very small relative afferent pupillary defect (rAPD)
Unilateral functional visual field loss	None (non-organic)	0.0	No real visual field loss
Central serous retinopathy or cystoid macular edema	Retina (fovea)	0.3	Area of retina involved, depth of scotoma
Central or branch retinal vein occlusion	Inner retina	0.3–0.6 (nonischemic) ≥ 0.9 (ischemic)	Area of visual field defect and degree of ischemia
Central or branch retinal artery occlusion	Inner retina	0.3–3.0	Area and location of retina involved
Retinal detachment	Outer retina	0.3–2.1	Area and location of detached retina (e.g., 0.6–0.9 log units for macula +0.3 log units for each quadrant)
Anterior ischemic optic neuropathy	Optic nerve head	0.6–2.7	Extent and location of visual field defect
Optic neuritis (acute)	Optic nerve	0.6–3.0	Extent and location of visual field defect
Optic neuritis (recovered)	Optic nerve	0.0–0.6	No visual field defect, residual relative afferent pupillary defect
Compressive optic neuropathy	Optic nerve	0.3–3.0	Extent and location of visual field defect, other eye involvement
Chiasmal compression	Optic chiasm	0.0–1.2	Asymmetry of visual field loss, unilateral central field involvement
Optic tract lesion	Optic tract	0.3–1.2 in the eye with temporal field loss	Incongruity of homonymous field defect, hemi-field pupillomotor input asymmetry
Postgeniculate damage	Visual radiations Visual cortex	0.0	Stimulus light size (no residual relative afferent pupillary defect but definite pupil perimetry defects)
Midbrain tectal damage	Olivary pretectal area of pupil light input region of midbrain	0.3–1.0	Similar to optic tract lesions, but no visual field defect
The expected magnitude of defect is given as well.			

to determine whether a patient's report of visual field defects is believable and trustworthy. Evaluating for an rAPD is very useful in the setting of functional vision loss because it is purely objective, although there is some subjectivity to most other tests, including visual acuity and visual fields. The correlation between visual field asymmetry and rAPD also is a useful monitor of the course of disease for a worsening or improvement in function. rAPDs are, by definition, differences in the input of one eye compared with that of the other. Bilateral symmetrical damage does not produce rAPDs. Thus, a definite rAPD in one eye on the first visit but no rAPD on follow-up may represent improvement in the previously damaged eye or the development of damage in the previously better eye. Therefore, it is always important to remember that the rAPD is, indeed, relative to the other eye.

Estimation of the amount of rAPD in log units (asymmetry between the two eyes) provides an idea of how much asymmetrical visual field damage is present and whether it is consistent with the results of the visual field test. In addition, the amount of rAPD may indicate whether the cause of damage is consistent with the results of the rest of the examination. For example, a patient affected by a small amount of macular degeneration in one eye and not the other is expected to have only a 0.3 log unit rAPD, but if that patient has a 1.2 log unit rAPD, then some additional cause of visual loss is likely, such as a previous branch retinal artery occlusion or optic neuropathy (Table 9.20.1).

The presence of a significant rAPD typically indicates either optic neuropathy or significant retinal disease. Decreased vision from cataract, cornea opacities, and refractive error do not cause a significant rAPD. Large amounts of intraocular hemorrhage can cause a small rAPD (see Table 9.20.1). Knowledge about the expected amount of rAPD can be helpful in this situation. For example, if an eye has light perception with a dense vitreous hemorrhage and has a 2.7 log rAPD (exceeding the expected amount of rAPD from a vitreous hemorrhage), the examiner would know there is significant retina or optic nerve pathology contributing to the vision loss, such as a retinal detachment or traumatic optic neuropathy, despite no view to the posterior pole.

In general, with unilateral visual loss, loss of the central 5° of the visual field results in an rAPD of approximately 0.3 log units. Loss of the entire central area of field (10°) causes an rAPD of 0.6–0.9 log units. Each visual field quadrant outside of the macula accounts for about 0.3 log units, but the temporal field loss results in more loss of pupillary input compared with loss in the nasal field quadrants because the normal temporal visual field extends to approximately 100° compared with 60° for nasal. The correlation between the relative afferent defect and the area and extent of visual field loss, however, is only approximate. Lack of correlation between the two may be important clues as to the cause and extent of damage to the anterior visual system. One example is recovered optic neuritis, where

a 0.3–0.6 log unit rAPD may be present with a normal automated visual field test. Another example is Leber's hereditary optic neuropathy (LHON), where the visual field loss may exceed the expected pupil deficit because of relative sparing of damage to the retinal ganglion cells subserving the pupil light reflex (intrinsically photosensitive retinal ganglion cells containing melanopsin). Studies that used computerized pupillography to quantify the rAPD more precisely showed that some subjects who have normal visual fields and examination results can have a small (0.3 log unit) rAPD.<sup>10–13</sup>

The amount of pupillomotor input asymmetry (the rAPD) may be estimated roughly by using the alternating light test and the subjective grades +1, +2, +3, or +4 (without any neutral density filters) for asymmetry of pupillary response. This subjective grading also may be categorized according to the amount of "pupil escape," or dilation of the pupils, as the light is alternated between the eyes.<sup>14</sup> However, most subjective grading of rAPDs have limitations, such as large-scale errors that arise from age variations in pupil size and pupil mobility. For example, a patient with small pupils and small pupillary contractions to light may have a large rAPD, but the asymmetry in pupil contraction may appear deceptively small on the basis of small differences in pupil excursion with alternating light between the two eyes. However, the amount of neutral density filter needed to dim the better eye until the small contractions are equal represents substantial input damage. More accurate quantification of rAPDs is accomplished by determination of the log unit difference needed to "balance" the pupil reaction between the two eyes<sup>4,5</sup> by using neutral density filters. Use of neutral density filters is more accurate and reproducible and can be used to objectively follow retinal and optic nerve functions.

To quantify the rAPD in log units, the asymmetry in pupil response is balanced by dimming the light shown into the better reacting pupil. A neutral density filter is held over the good eye and the alternating light test repeated. If the input asymmetry is still visible, the density of the filter over the good eye is increased until the amplitudes of the direct light reactions of the two eyes are balanced. To be certain of the measurement, the balance point may be overshoot deliberately and then back titrated. When a dense filter is used, it may be necessary to look behind the filter to see the pupil. Unfortunately, the pupillary response to a repeated light stimulus is far from constant; it changes from moment to moment.<sup>10,11</sup> A common error is to judge the apparent asymmetry of the light reflex too quickly. It is important to alternate the light back and forth at least three times to obtain a mental average of any asymmetry. In this way, moment-to-moment fluctuations in the pupillary response are "averaged out." Despite such efforts, the afferent asymmetry may still fluctuate slightly with time, even when carefully recorded by using computerized pupillography.

Optic neuropathy and retinal disease causing an rAPD will not result in anisocoria. However, the presence of anisocoria can make evaluation of an

**Fig. 9.20.2 Parasympathetic and Sympathetic Innervation of the Iris Muscles.**

rAPD more difficult, and therefore the examiner first needs to check for the presence of anisocoria to ensure that either eye's pupil contraction can be observed during the alternating light test. For example, the presence of an efferent pupil defect and the resulting anisocoria may be mistaken for an apparent rAPD if the pupil response of the eye being illuminated is observed during the rAPD test. If one sphincter is weak, the investigator may still check for an afferent defect by just observing the pupil that still works as the light is alternated between the two eyes, by comparison of its direct and consensual reactions (reverse rAPD technique). While a measurement is made, the good eye is behind the filter, and it may be hard to see the pupil. Sometimes it is necessary to use a side light on the healthy iris to see its consensual pupil reaction. In addition, anisocoria may influence the estimate of pupillary input asymmetry, especially in the case of darkly pigmented irises. A small pupil in one eye will allow less light to pass and will reduce retinal illumination compared with the other eye with the larger pupil, producing an rAPD in the eye with the smaller pupil.

Infants and small children pupils are most easily checked at about 3 ft (1 m) away with a direct ophthalmoscope. In a dark room, the brightest light is used, focus is on the red reflex, and the light is alternated from eye to eye. The baby usually is fascinated by the light, which helps facilitate the pupil examination.

## EFFERENT PUPILLARY DEFECTS

### Anisocoria

As discussed above, a pupillary inequality usually indicates that either the iris muscle or its innervation is damaged (Fig. 9.20.2). To be able to identify the weaker muscle, it is useful to know how the anisocoria is influenced by light. Anisocoria always increases in the direction of action of the paretic iris muscle, just as esotropia increases when gaze is in the direction of action of a weak lateral rectus muscle. Therefore, one of the first important diagnostic approaches to understanding the cause of anisocoria is to observe whether the pupil inequality increases in dark or in light (Fig. 9.20.3).

### Pupillary Inequality That Increases in the Dark

In patients who have a pupillary inequality that increases in dim light (see Fig. 9.20.3), the problem is to differentiate oculosympathetic paresis (Horner's syndrome) from physiological anisocoria (or simple anisocoria)—in which the inequality also is greater in dim light. Patients with a small pupil from functional or mechanical restriction to dilation from synechiae, "little old Adie pupil," cholinergic miosis, or congenital miosis can be easily identified because the pupil will not dilate properly in the dark or with sympathomimetic drops compared with the fellow eye.

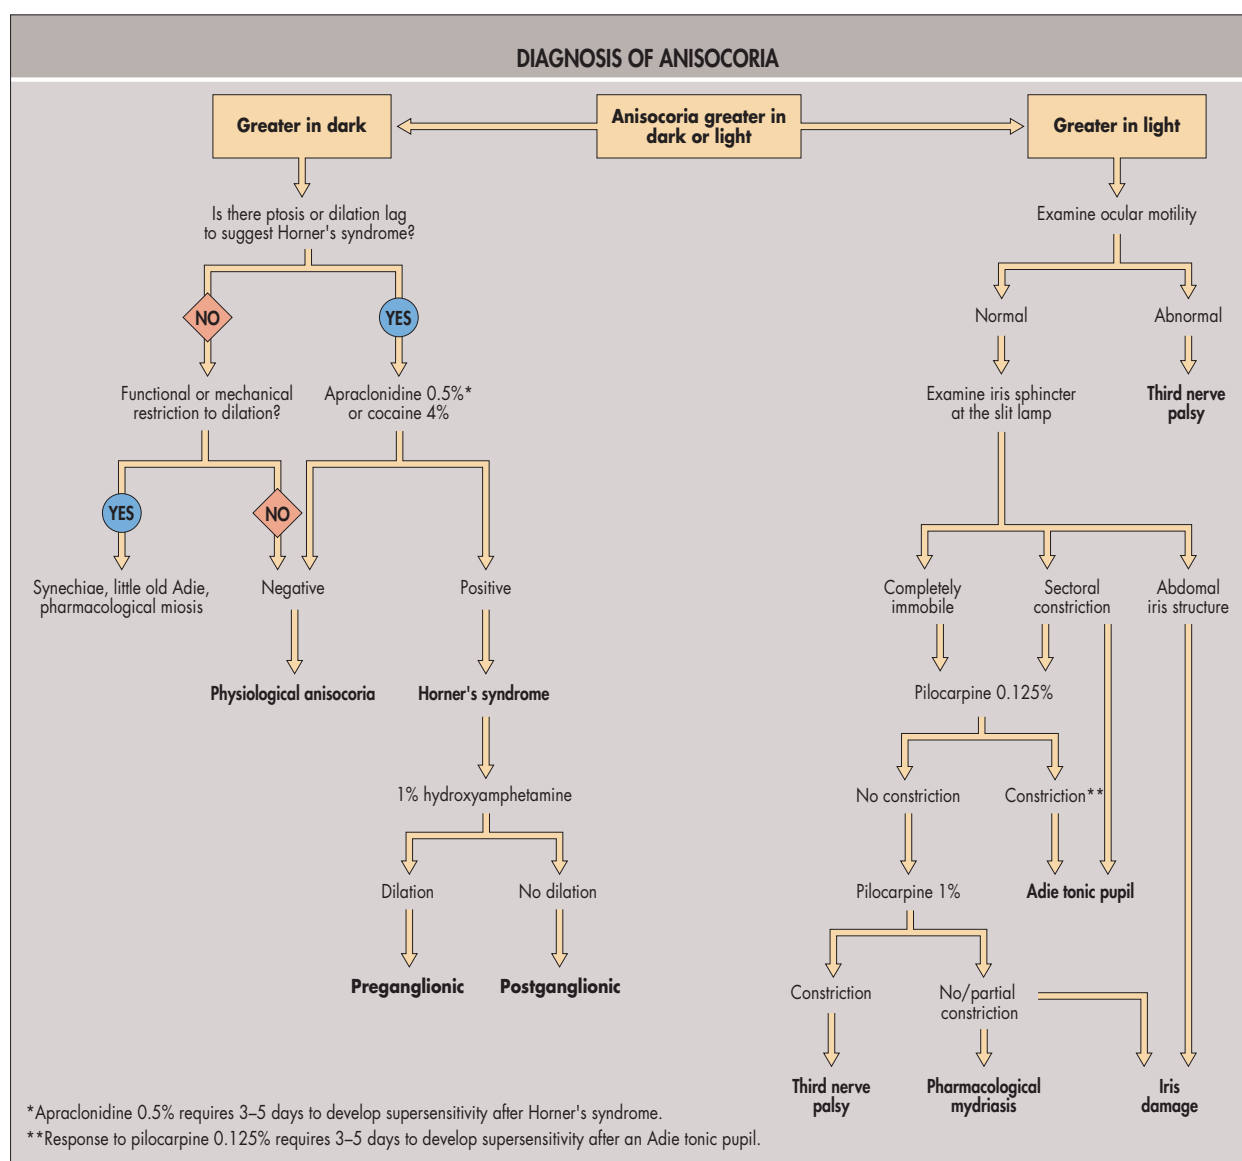

#### Physiological Anisocoria

Physiological anisocoria is common and can be visible in about one fifth of the normal population and is not associated with disease or refractive error. Physiological anisocoria may vary from day to day, or even from hour to hour. About 10% of normal subjects, examined in room light, have an anisocoria of 0.4 mm or more. Physiological anisocoria also, like Horner's syndrome, decreases slightly in light, but it does not show a dilation lag of the smaller pupil and is not accompanied by ptosis or facial anhidrosis. It is believed that physiological anisocoria most likely arises from asymmetrical inhibition at the Edinger-Westphal nucleus in the midbrain. Normally, during wakefulness some inhibition from the reticular activating formation keeps the pupils midsize or larger. During sleep, this inhibition fades and allows the neurons in the Edinger-Westphal nucleus to discharge, which results in miotic pupils. If, during wakefulness, the inhibition is greater to the right Edinger-Westphal nucleus than the left, the right pupil is larger, especially in dim light. When light is added or a near reflex is generated, this inhibition is overcome, the pupils become smaller, and any asymmetrical inhibition diminishes. A reduction of the anisocoria results as the pupils become smaller.

#### Horner's Syndrome

Horner's syndrome is caused by damage to the oculosympathetic pathway, which clinically manifests as ipsilateral miosis, facial anhidrosis, ptosis, "upside-down ptosis" of the lower lid, and, in an acute case, conjunctival

**Fig. 9.20.3 Diagnosis of Anisocoria.** If the anisocoria is greatest in dim light and diminishes in bright light, then the pupillary inequality is usually either physiological (simple anisocoria) or arises from the loss of sympathetic innervation to the dilator muscle (Horner's syndrome). If anisocoria is greater in bright light than in the dark, this indicates that the sphincter of the large pupil is weak or that a parasympathetic lesion is present on that side. A few other conditions need to be considered, but this chart is concerned only with acute damage to a single intraocular muscle or its innervation. (Material adapted and figure created from Focal points: Clinical Modules for Ophthalmologists: Anisocoria, Vol. XXXI, Number 3. American Academy of Ophthalmology; 2013.)

**Fig. 9.20.4 Horner's Syndrome Clearly Acquired in Infancy Must Be Evaluated for Neuroblastoma, a Treatable Tumor.** This baby, with a right ptosis and miosis, developed a flush during cycloplegia that made the vasomotor abnormality very clear—the Horner's syndrome side remained pale. The baby had no sign of Horner's syndrome during her first 8 months, but at 16 months, Horner's syndrome is obvious (ptosis, miosis, and upside-down ptosis). Because the syndrome was acquired, chest radiography was ordered; it showed a mass in the pulmonary apex. Magnetic resonance imaging confirmed the lesion. Surgery revealed a neuroblastoma.

injection and lowered intraocular pressure. The ptosis results from interruption of the sympathetic innervation of Müller's muscle (see Figs. 9.20.2 and 9.20.3; Fig. 9.20.4). The ptosis of Horner's syndrome is mild to moderate and never complete. The pupil is miotic in Horner's syndrome because the sympathetic innervation to the iris dilator muscle is disrupted.

The miotic pupil from Horner's syndrome is more apparent in the dim lighting conditions and has a characteristic "dilation lag," which can be seen in the office by using a handheld light shined from below. The room lights are switched off, and the smaller pupil is examined for an apparent reluctance to dilate. Pupil dilation is normally a combination of sphincter relaxation and dilator contraction, a combination that produces a prompt dilation. The patient who has Horner's syndrome has a weak dilator muscle in one iris as a result of the disruption of sympathetic innervation

and, as a result, that pupil dilates more slowly than the normal pupil. If the sympathetic lesion is complete, the affected pupil dilates only by sphincter relaxation. The resultant asymmetry of pupil dilation produces an anisocoria that is largest 4–5 seconds after the lights have been turned out—the process is much slower than is generally thought. At 10–20 seconds after the lights have been turned off, the anisocoria lessens as the sympathetomized pupil gradually catches up, a process referred to as *dilation lag*. The test is a quick and simple way to differentiate Horner's syndrome from physiological anisocoria. It works well most of the time, particularly in young people who have mobile pupils. Pharmacological testing with either cocaine eyedrops or topical apraclonidine is typically used to confirm the diagnosis of Horner's syndrome.

### Diagnosis of Horner's Syndrome—Cocaine and Apraclonidine Pharmacological Testing

The action of cocaine is to block the reuptake of norepinephrine (noradrenaline) normally released from the nerve endings. If norepinephrine is not released because of an interruption in the sympathetic pathway, cocaine has no adrenergic effect. Therefore, the affected pupil in a patient with Horner's syndrome dilates less with cocaine compared with the normal pupil, regardless of the location of the lesion. Cocaine drops are placed in both eyes. If the anisocoria has increased clearly after 60 minutes, this confirms Horner's syndrome because the normal pupil has dilated more compared with the pupil in Horner's syndrome. If there is at least 0.8 mm of pupillary inequality after cocaine administration, Horner's syndrome is highly likely.<sup>15</sup> If very little dilation of the pupil occurs, even though an oclosympathetic defect is suspected, and the pupil did not dilate well before the cocaine test even after 30 seconds in darkness, then a false-positive cocaine test result must be considered. A false-positive result may occur if the iris is held in a miotic state through either scarring or aberrant

reinnervation of the iris sphincter. If this is suspected, the addition of a direct-acting sympathomimetic agent to both eyes (e.g., 2.5% phenylephrine) at the conclusion of a positive cocaine test should dilate the suspected eye easily and eliminate the cocaine-induced anisocoria after 30 minutes in Horner's syndrome, whereas a structural cause of miosis would not cause the eyes to dilate.

Topical apraclonidine has gained popularity as an alternative to cocaine testing for the diagnosis of Horner's syndrome.<sup>16-21</sup> Unlike cocaine, apraclonidine is not a controlled substance, is easier to obtain and use in a doctor's office, and produces mydriasis in the eye with oculosympathetic paresis from Horner's syndrome as a result of denervation adrenergic supersensitivity. Typically, 45 minutes following topical 0.5% apraclonidine administered to both eyes, the miotic eye with Horner's syndrome dilates and the anisocoria reverses. In most cases, the normal unaffected eye becomes smaller in dim light. This is because apraclonidine is primarily an  $\alpha_2$ -adrenergic agonist, causing inhibition of norepinephrine release at the presynaptic terminus and slight miosis in the normal eye. However, it is also a weak  $\alpha_1$ -adrenergic agonist, and in the presence of adrenergic denervation supersensitivity, it causes mydriasis, as is the case in the eye with Horner's syndrome. In patients with anisocoria of other causes, such as physiological anisocoria, apraclonidine has very little effect on the anisocoria. Apraclonidine has an advantage over cocaine in that it will actively dilate the affected eye and not the normal eye, making its action a positive (mydriatic) one in the affected eye, unlike in the case of cocaine, which causes negative action in the affected eye and positive (mydriatic) action in the unaffected eye. Thus, a positive apraclonidine test result causes a reversal of anisocoria in Horner's syndrome (or significant reduction of anisocoria in milder cases), which is easier to see than an increase in anisocoria expected with a positive cocaine test result. Another advantage of apraclonidine is that it will also reverse the ptosis in Horner's syndrome within minutes because of its activity on Müller's muscle, which is also innervated by the sympathetic pathway and becomes supersensitive in Horner's syndrome. After lack of sympathetic activity, adrenergic supersensitivity usually occurs between 2 and 5 days. Therefore, in very acute cases, cocaine is still preferred for pharmacological confirmation of Horner's syndrome. On a cautionary note, there have been a small number of reports of respiratory depression in infants exposed to topical apraclonidine because of its ability to cross the blood-brain barrier, similar to bromonidine, and is therefore contraindicated in infants unless the infant can be monitored for 4-5 hours after testing. Therefore, testing in children is more commonly performed with cocaine because of this possible serious side effect of apraclonidine.

### Location of Damage to the Sympathetic Pathway

After the diagnosis of Horner's syndrome is made, localizing whether the damage is along the preganglionic or postganglionic sympathetic pathway helps direct imaging, if indicated. Horner's syndrome sometimes manifests so characteristically that further efforts to localize the lesion are superfluous, as with patients with cluster headaches or patients with a history of surgery or trauma along the sympathetic pathway. Localization of a sympathetic lesion is a question of considerable clinical importance because many postganglionic defects are caused by vascular headache syndromes, cavernous sinus pathology, or carotid dissections, and preganglionic lesions sometimes result from malignant tumors or strokes to the central sympathetic location in the brain. These findings can assist the radiologist in interpretation of any diagnostic imaging. Pharmacological testing with hydroxyamphetamine drops can be helpful in localizing the lesion as well.

Hydroxyamphetamine releases norepinephrine from storage vesicles in the postganglionic sympathetic nerve endings at the iris dilator muscle. When the lesion is postganglionic, the third order nerve is dead, and no norepinephrine stores are available for release at the iris. When the lesion is complete, the pupil does not dilate at all. However, the dying neurons and their stores of norepinephrine may last for almost 1 week from the onset of damage. Therefore, a hydroxyamphetamine test administered within 1 week of a postganglionic lesion may give a false preganglionic localization if some of the norepinephrine stores remain. When Horner's syndrome is caused by preganglionic or central lesions, the pupils dilate normally because the postganglionic third order neuron and its stores of norepinephrine, although disconnected, are still intact.

To perform the hydroxyamphetamine test, the pupil diameters are measured before and 60 minutes after hydroxyamphetamine drops have been placed in both eyes. The change in anisocoria in room light is noted. If the affected pupil—the smaller one—dilates less compared with the normal pupil, an increase in anisocoria occurs, and the lesion is in the

postganglionic neuron. If the smaller pupil now dilates so much that it becomes the larger pupil, the lesion is preganglionic and the postganglionic neuron is intact. The examiner must wait at least 48 hours after cocaine has been used before the administration of hydroxyamphetamine; cocaine inhibits the uptake of hydroxyamphetamine into the presynaptic sympathetic nerve terminal and seems to block its effectiveness. In general, if the anisocoria increases by at least 0.5 mm after hydroxyamphetamine administration, the lesion is most likely postganglionic. A decrease in anisocoria points toward a preganglionic location of the lesion. However, hydroxyamphetamine is no longer commercially available, and there are rare reports of false localization with hydroxyamphetamine. For these reasons, many clinicians forgo further localizing with hydroxyamphetamine and image the entire sympathetic pathway unless history or associated signs and symptoms clearly localize the lesion. For instance, acute Horner's syndrome with associated ipsilateral neck or facial pain requires urgent imaging of the neck for evaluation of a carotid dissection.

### Horner's Syndrome in Children and Infants

When a child is observed to have a unilateral ptosis and miosis, the first question is to ascertain whether Horner's syndrome is present and, if present, whether it was acquired or was present at birth. A child who has congenital Horner's syndrome and naturally curly hair has, on the affected side of the head, hair that seems limp and lank. The shape of the hair follicles depends on intact sympathetic innervation, as does the iris pigment. Iris melanocytes, derived from the neuroectoderm, require sympathetic innervation to produce melanin, and if the innervation is not present at birth or interrupted during the first year of life, a lighter iris will occur, resulting in heterochromia. However, a child with Horner's syndrome who has blond, straight hair and very pale, blue eyes will not have any visible asymmetry of hair straightness or iris heterochromia. These signs are typically seen in congenital Horner's syndrome but can be rarely seen in acquired Horner's syndrome.

The most telling symptom is the hemifacial flush (blanch on the affected side) that occurs with nursing or crying. Generally, the affected side is pale. In an air-conditioned office, it may be hard to decide whether sweating is decreased on the affected side. A cycloplegic refraction sometimes produces an atropinic flush everywhere except on the affected face and forehead and, thus, provides additional evidence toward diagnosis because of lack of sympathetic innervation to the skin vasculature. When the pupil, eyelid, and skin signs of Horner's syndrome are equivocal, pharmacological testing is needed to make the diagnosis with more certainty. Because of the possible central nervous system depression that can occur with apraclonidine, cocaine testing is generally used (see above section on cocaine testing) and occlusion of the punctae of the tear ducts after cocaine drops will reduce the low risk of systemic side effects even further.

Making a diagnosis of Horner's syndrome in infancy or childhood is important because these patients must be evaluated for neuroblastoma—a treatable tumor (see Fig. 9.20.4), unless there is a known history of surgery in the area of the sympathetic chain to explain Horner's syndrome.

### Pupillary Inequality That Increases With Light

For a patient who has pupillary inequality that increases with light, several problems must be addressed (see Fig. 9.20.3). The diagnostic evaluation is usually focused on whether the efferent pupil defect is caused by denervation, direct damage to the iris sphincter muscle, or pharmacological mydriasis.

### Slit-Lamp Examination of the Iris

Trauma to the globe usually results in a torn sphincter and an iris border that transilluminates at the slit lamp, showing small divots. The pupil is often not round and may show segmental areas of sphincter immobility, similar to an Adie's pupil (see below); other evidence of ocular injury may also be present. Naturally, such a pupil does not constrict well to light. An atrophic sphincter caused by previous herpes zoster iritis also may reveal transillumination defects, as seen with the slit lamp, that arise from previous ischemic insults to the iris. An irregular pupil with a sectoral immobility may also be a sign of iridocorneal endothelial (ICE) syndrome. If, however, the iris looks normal, further investigation is required, as outlined below.

### No or Little Residual Light Reaction

If no residual light reaction is present, the possibility of pharmacological mydriasis must be explored.<sup>22</sup> However, a completely blocked light reaction sometimes may occur when the sphincter is denervated by either a

preganglionic lesion (third nerve palsy) or a postganglionic lesion (acute, complete tonic pupil), in acute angle closure (iris ischemia), or with an intraocular iron foreign body (iron mydriasis). If the dilated pupil still has some response to light, the dilation may result from partial denervation of the sphincter, incomplete atropinization, or adrenergic mydriasis. When the light reaction is poor because the dilator muscle is in spasm (as a consequence of adrenergic mydriatics, such as phenylephrine, or in some patients with acute migraine), then the pupil is very large, the conjunctiva is blanching, and the lid is retracted. In such cases, any decrease in the amplitude of accommodation is minor.

### Segmental Paralysis of the Iris Sphincter

When some residual light reaction occurs, the iris sphincter is examined for sector palsy by using the slit lamp. When the dilator is in a drug-induced adrenergic spasm or when an atropine-like drug blocks the cholinergic receptors in the iris sphincter, the entire sphincter muscle (all 360°) is affected. This usually does not happen when postganglionic parasympathetic nerve fibers have been interrupted in Adie's syndrome. In patients with Adie's syndrome, there is usually at least one sector of the iris sphincter showing a residual light reaction at the slit lamp, causing the so-called *vermiform movement*. Thus, a pupil that has a weak light reaction and no segmental palsy usually indicates a drug-induced mydriasis, or resulting from a third cranial nerve paresis (preganglionic parasympathetic nerve), which may require more extensive investigations.

### Pupillary Supersensitivity to Cholinergic Drugs

If weak pilocarpine (about 0.1%) is applied to both eyes (with both corneas healthy and untouched), and the affected (mydriatic) pupil constricts more than the normal pupil to become the smaller pupil in dim light after 30 minutes, it can be concluded that the iris sphincter is showing denervation cholinergic supersensitivity. Cholinergic supersensitivity can occur within days of denervation. It seems likely that with a postganglionic denervation (ciliary ganglion to the eye), the sphincter will show a little more supersensitivity than in the preganglionic case (third nerve palsy); however, the differences are not great and therefore cannot be used to differentiate Adie's syndrome from a pupil involving third nerve palsy. Cholinergic supersensitivity of the iris sphincter is considered now to be only a weak sign of Adie's syndrome. As the iris sphincter is reinnervated by cholinergic accommodative fibers and becomes smaller over time, supersensitivity can be lost.<sup>23</sup>

It is very rare for an ambulatory patient to have an isolated sphincter palsy caused by damage to the intracranial third nerve without ptosis or diplopia. However, a patient should be warned that if ptosis or double vision does develop, a prompt re-evaluation should be undertaken for compression of the oculomotor nerve. If the normal pupil constricts a little to dilute pilocarpine and the dilated pupil does not constrict at all, the mydriasis may be the result of a local dose of an anticholinergic drug, such as atropine. A stronger concentration of pilocarpine showing no or little pupil constriction would confirm this.

### Pupillary Undersensitivity to a Miotic Dose of Pilocarpine

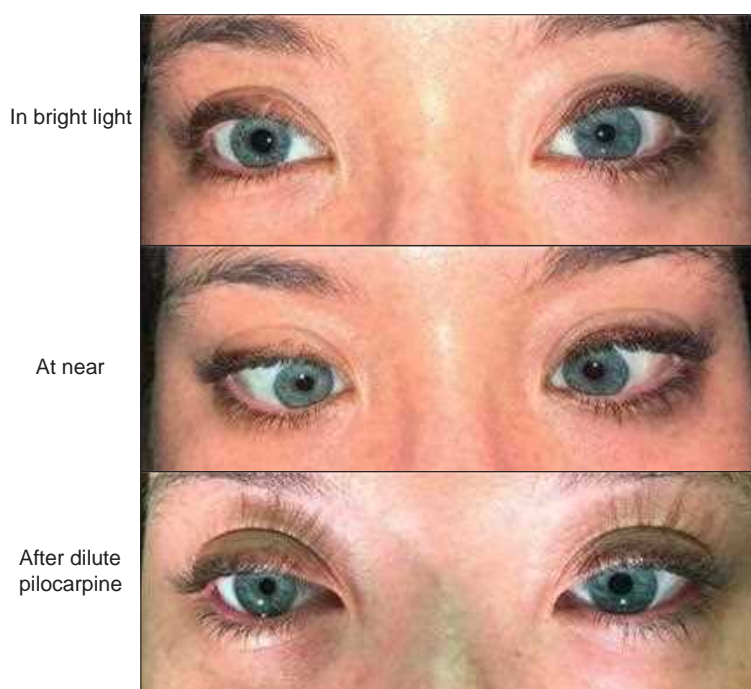

If the affected pupil reacts little or not at all and the unaffected pupil constricts normally on application of pilocarpine 1% in each eye, then the mydriasis is likely caused by a problem with the sphincter muscle itself and not because of denervation. Non-neuronal causes of mydriasis are as follows:

- Anticholinergic mydriasis (e.g., scopolamine (hyoscine), cyclopentolate, atropine).
- Traumatic iridoplegia (sphincter rupture, pigment dispersion, angle recession).
- Angle-closure glaucoma (ischemia of the iris sphincter).
- Fixed pupil after anterior segment surgery.
- Bound down iris (synechia) after iritis or as a result of ICE syndrome.

The cause for complete loss of function of the iris muscles after anterior segment surgery is unknown. An excessive rise in intraocular pressure during or after surgery can sometimes cause ischemic damage to the iris sphincter.

### Tonic Pupil of Adie's Syndrome

Young adults (more women than men) may present with one pupil that is large or with a complaint that they are not able to focus up close with one eye because of Adie's syndrome, which results from an injury, often idiopathic, to the ciliary ganglion or short ciliary nerves. Slit-lamp examination

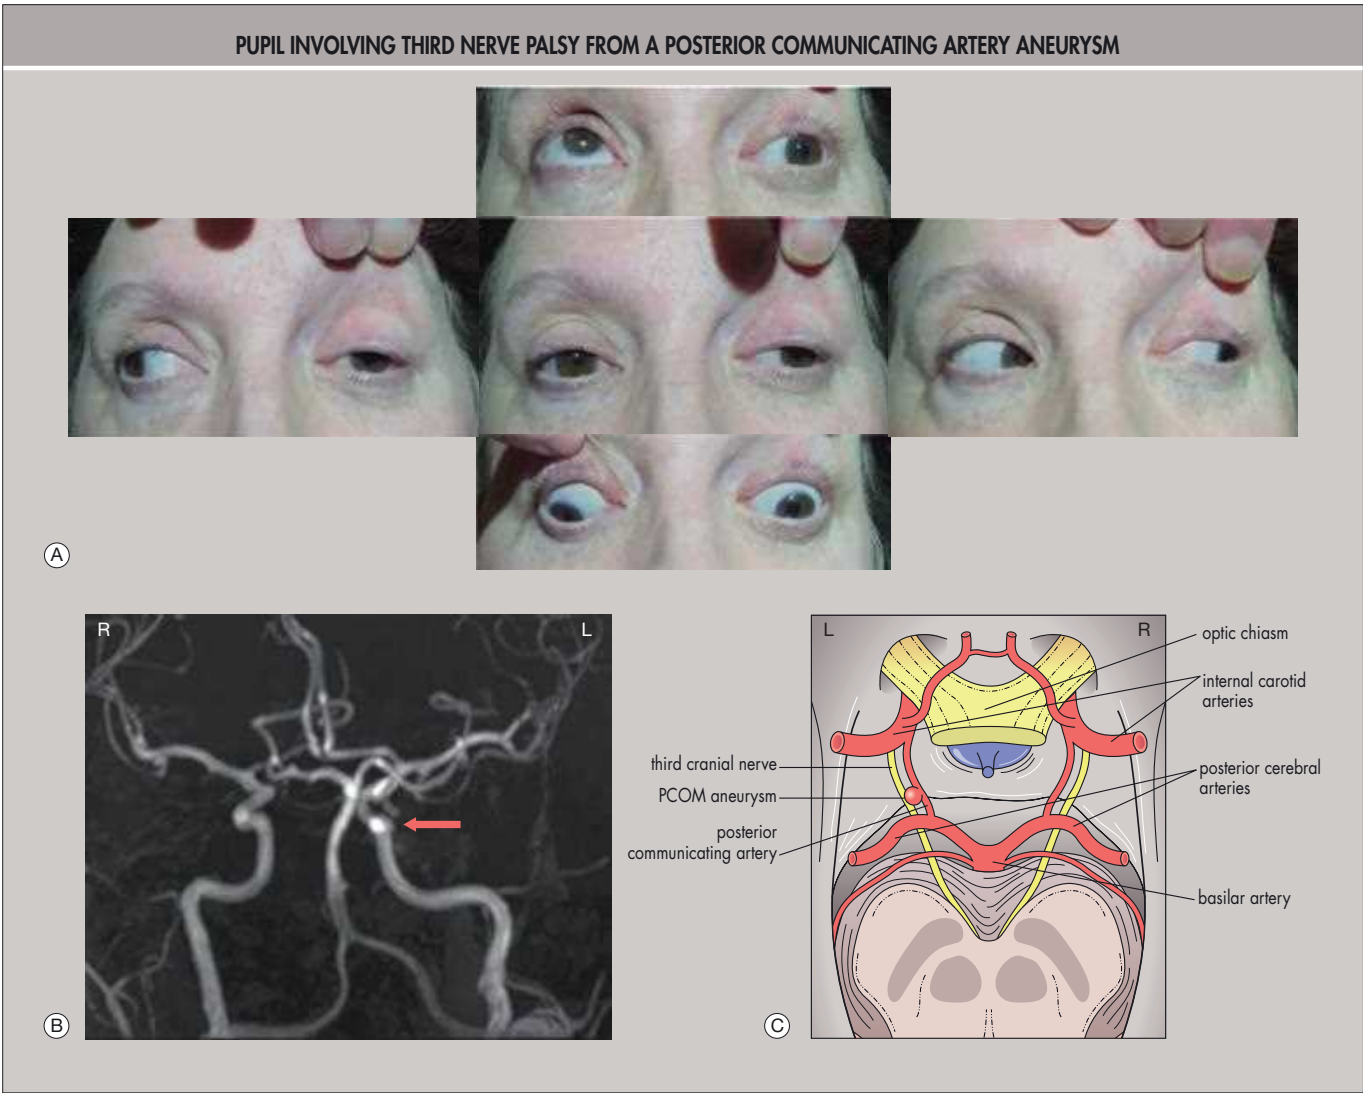

**Fig. 9.20.5 Adie's Syndrome.** This patient has a right Adie's syndrome that has been present for 1 year. With time, there has been aberrant regeneration of the accommodative post-ganglionic parasympathetic fibers to the iris sphincter, in addition to re-innervation to the ciliary muscle, causing a tonic pupil contraction to a near effort without return of the light reflex, resulting in a light-near dissociation of the pupil. Dilute pilocarpine results in reversal of the anisocoria because of the hypersensitivity.

usually shows segmental denervation of the iris sphincter. Within the first week, supersensitivity to cholinergic substances may be demonstrated. After about 2 months, nerve regrowth is active and fibers originally bound for the ciliary muscle (they outnumber the sphincter fibers by 30:1) start to arrive (aberrantly) at the iris sphincter, and this produces the characteristic light-near dissociation of Adie's syndrome (Fig. 9.20.5). Eventually, the affected pupil becomes the smaller of the two pupils, especially in dim light, because of the aberrant reinnervation by accommodative fibers ("little old Adie pupil"). The segmental palsy of the iris sphincter is seen particularly well by using infrared video recording of transillumination of the iris.<sup>23</sup> Patients with Adie's syndrome also often have impaired deep tendon reflexes.

### Third Nerve Palsy

A pupil involving third nerve palsy is considered a neurological emergency because a small percentage of these are caused by life-threatening aneurysms (Fig. 9.20.6). An old clinical rule of thumb is that if the pupillary light reaction is spared, the third nerve palsy probably does not result from compression or injury, but more likely from small vessel disease, as may be seen in diabetes. It would be exceedingly rare for compression, especially from a posterior communicating artery aneurysm, to cause complete external dysfunction with pupil sparing because the pupillary fibers run along the dorsomedial surface of the nerve. However, there are multiple reports of aneurysms causing a partial pupil sparing third nerve palsy initially, which later worsen to involve the pupil and have the risk for potential catastrophic rupture. Therefore patients with a partial pupil-sparing third nerve palsy require urgent neuroimaging to rule out an aneurysm.<sup>24</sup> Approximately 16% of microvascular third nerve palsies have visible anisocoria, so pupil involvement does not necessarily mean a compressive lesion.<sup>25</sup> Finally, a very small number of pupil-sparing third cranial nerve palsies arise from midbrain infarcts, although these are typically accompanied by other neurological signs or symptoms, such as contralateral weakness. It is extraordinarily rare for an acute pupil involving third nerve palsy to show segmental palsy; acute cases show partial to complete efferent pupil defects that are symmetrically palsied around the circumference of the sphincter muscle. In addition, almost all cases of pupil involving third nerve palsy will have other elements of oculomotor dysfunction, including ptosis or extraocular motility deficits. Therefore, patients with isolated pupillary dilation do not require neuroimaging for aneurysms.<sup>24</sup>

**Fig. 9.20.6 Pupil Involving Third Nerve Palsy From a Posterior Communicating Artery Aneurysm.** This patient had an acute painful left pupil involving third nerve palsy with pupil dilation, ptosis, and deficits in elevation, adduction, and depression from a posterior communicating artery aneurysm (red arrow). The diagram demonstrates the close relationship between the posterior communicating artery aneurysm and the third cranial nerve. A pupil-involving third nerve palsy is compression, until proven otherwise.

### Aberrant Regeneration of the Third Cranial Nerve

The third cranial nerve carries instructions to several different muscles, so when the nerve is injured and the fibers regrow, they may grow into the wrong location. This most commonly occurs when the glial scaffolding, which normally segregates nerve bundles, is disrupted by trauma or external compression by a tumor. For example, the eye may inappropriately turn in when the patient is trying to look down or up, or the pupil may inappropriately constrict with depression, adduction, or supraduction of the globe. This does not occur with microvascular third nerve palsies, and therefore, aberrant regeneration outside of trauma is compression until proven otherwise.

### POOR PUPIL DILATION

When one or both pupils stay small and miotic, even in darkness, a number of factors may be responsible (Table 9.20.2). To better understand the different possible mechanisms, it is important to understand the normal process that allows the pupil to dilate in darkness. When a light stimulus is terminated, two mechanisms cause the pupil to dilate. The greater part of pupil dilation arises from inhibition to the Edinger–Westphal nucleus in the midbrain, which reduces the firing of the preganglionic parasympathetic neurons in the Edinger–Westphal nucleus and results in relaxation of the iris sphincter. Within a few seconds, sympathetic nerve firing increases, which augments the pupil dilation by active contraction of the dilator muscle. The combined inhibition of the iris sphincter and stimulation of the iris dilator is a carefully integrated neuronal reflex. Therefore, inability of the pupil to dilate in darkness may occur because of a sympathetic nerve palsy, mechanical limitations of the pupil (scarring),

**TABLE 9.20.2 Causes of Poor Pupil Dilation in Darkness**

Cause	Location	Mechanism
Past inflammation or surgical trauma	Posterior iris surface or sphincter	Scarring or synechiae of the iris because of past iritis
Acute trauma	Sphincter	Prostaglandin release causes sphincter spasm
Adie's syndrome tonic pupil Third cranial nerve aberrant reinnervation	Sphincter	Aberrant regeneration of iris sphincter by accommodative or extraocular motor neurons that are not inhibited in darkness
Pharmacological miosis	Iris sphincter	Cholinergic influence
Unilateral episodic spasm of miosis	Postganglionic parasympathetic neuron	Uninhibited episodic activation of postganglionic neurons
Congenital miosis (bilateral)	Sphincter	Developmental abnormality
Fatigue, sleepiness	Edinger–Westphal nucleus	Loss of inhibition at midbrain from reticular activating formation
Lymphoma, inflammation, infection	Periaqueductal gray matter	Interruption of inhibitory fibers to the Edinger–Westphal nucleus
Central-acting drugs	Reticular activating formation, midbrain	Narcotics, general anesthetics
Old age (bilateral miosis)	Reticular activating formation, midbrain	Loss of inhibition at midbrain from reticular activating formation
Oculosympathetic defect	Sympathetic neuron interruption	Horner's syndrome

**Fig. 9.20.7 Pupil Light Reflexes to Red and Blue Lights as a Function of Light Intensity—The Melanopsin-Mediated Sustained Response to Blue Light.** Pupil tracings are shown for pupil light reflexes in response to a one-second duration red light (red tracings) or blue light (blue tracings) that increases in intensity. As the light intensity increases, the pupil contraction increases in amplitude. At the brightest light intensity, the pupil contraction becomes very sustained with blue light but not with red light, representing a signature of intrinsic activation of a melanopsin-mediated pupil response.

pharmacological miosis, aberrant reinnervation of cholinergic neurons to the iris sphincter that are not normally inhibited in darkness (accommodative or extraocular motor neurons), or inhibitory input signal not received by the Edinger–Westphal nucleus.

## RETINAL ORIGIN OF THE PUPIL LIGHT REFLEX—THE MELANOPSIN-CONTAINING RETINAL GANGLION CELL

Recent evidence has shown that almost all of the rod and cone input to the pupil light reflex is mediated by a special class of retinal ganglion cells containing the primitive visual pigment melanopsin found in the retina of lower animals.<sup>26–47</sup> Besides being activated by rod and cone input causing a transient pupil response, the melanopsin retinal ganglion cell is itself also directly sensitive to light (peak sensitivity is in the blue wavelength range), providing a sustained steady-state pupil constriction to light (Fig. 9.20.7). This intrinsic, direct activation pathway of the melanopsin-containing retinal ganglion cells causes the cell to discharge in a sustained way and is directly proportional to steady-state light input, similar to a direct-current light meter, which does not show the classic light adaptation properties.

In genetically altered mice that completely lack functional rods and cones, it was discovered that a rather robust pupil light reflex was still present. This unexpected finding was followed by a series of studies to identify what retinal element could be contributing to the pupil light reflex in the absence of rod and cone input. Through clever labeling experiments, a specific ganglion cell was identified as containing melanopsin, which was itself photosensitive, with a broad spectral peak centering on about 490 nm. Elegant electrophysiological recordings coupled with the study of response properties of these ganglion cells have revealed that the melanopsin-containing retinal ganglion cells project to the pretectal nucleus (the site of the first midbrain interneuron synapse for the pupil light reflex pathway) and also provide light sensing information for the diurnal regulating areas of the hypothalamus (suprachiasmatic nucleus) that modulate the circadian rhythm and other important light-modulated biological functions. More recently, a number of subtypes of melanopsin-containing retinal ganglion cells, which appear to have preferential activating properties and projections to the brain, have been identified. Studies have recently shown that patients with Alzheimer's disease have significant loss of melanopsin-containing retinal ganglion cells, and this factor may be a large contributor to the circadian rhythm dysfunction seen in Alzheimer's disease.<sup>38</sup> In addition, patients with multiple sclerosis were shown to have a decrease in the melanopsin-mediated pupillary

light reflex that correlates with ganglion cell layer thinning, which could put patients at risk for retinohypothalamic dysfunction.<sup>39</sup> Other conditions, such as mitochondrial optic neuropathies have a selective sparing of the melanopsin ganglion cells, which can explain the preserved pupillary light reflex in some patients with LHON and dominant optic atrophy.<sup>40</sup>

In addition to receiving rod and cone input to the pupil light reflex, melanopsin ganglion cells are capable of transduction of light directly, without photoreceptor input, and are likely responsible for providing more steady-state light input information to the brain. This helps explain why some patients blind because of photoreceptor loss still exhibit both a pupil light reaction to bright blue light and also maintain a circadian rhythm, whereas patients blind because of optic nerve lesions (loss of melanopsin ganglion cell input) are often lacking a normal circadian rhythm. By adjusting the state of adaptation (dark adaptation versus light adaptation), the light intensity, the duration of the light stimulus (i.e., 1 second) and the peak wavelength of the light stimulus (i.e., red versus blue light), one can record pupil contractions that are primarily rod mediated, cone mediated, and melanopsin mediated, which can be useful in detecting disorders of different classes of photoreceptors<sup>41–46</sup> or more distal disorders<sup>47</sup> in a clinical setting.

# Presbyopia and Loss of Accommodation

# 9.21

Sean P. Donahue, Reid A. Longmuir

**Definition:** Loss of accommodation, the ability of the eye to increase its refractive power, may occur as a result of the age-associated decrease in elasticity of the natural lens (presbyopia), or from other less common causes.

**Key Feature**

- Blurred vision at near.

**Associated Features**

- Advanced age.
- Drug use (cholinergics, botulism).
- Other rare causes.

**INTRODUCTION**

Accommodation is the ability to increase the refractive power of the optical system of the eye. It is necessary to produce a clear retinal image of objects that are near. For accommodation to occur, the ciliary body contracts, the lens zonules relax, and the crystalline lens assumes a more spherical shape, which increases its refractive power.

Presbyopia is by far the most common cause of loss of accommodation. Although age-associated loss of elasticity of the lens and lens capsule has been implicated, the true pathogenesis remains obscure. Disorders other than presbyopia can affect accommodation but are, for the most part, relatively rare.<sup>1</sup>

**EPIDEMIOLOGY AND PATHOGENESIS**

The neural pathway for accommodation probably begins in the midbrain. Attempts at accommodation are associated with convergence and pupillary miosis (the “near triad”), so the areas responsible for accommodation are probably related closely to those that produce convergence. These areas receive input from the cerebral cortex and pretectum; complex pathways project symmetrically to the portion of the third cranial nerve nucleus responsible for accommodation, probably in the caudal segment of the Edinger–Westphal parasympathetic nucleus.<sup>2,3</sup> These fibers then travel from the third cranial nerve nucleus to the ciliary ganglion, where they synapse with postganglionic parasympathetic fibers destined for the ciliary body and iris sphincter. They reach the intrinsic muscles of the eye via the short ciliary nerves. It is possible that a direct (nonsynapsing) pathway from the midbrain to the ciliary body also exists.

The ciliary body also receives sympathetic input, as evidenced clinically by the increased accommodative amplitude seen in the affected eye of patients with Horner’s syndrome. However, parasympathetic control is of much greater clinical importance.<sup>3</sup>

Because accommodation is mediated almost exclusively via parasympathetic pathways, it is antagonized best with muscarinic blockers. Five muscarinic antagonists are commonly used in ophthalmology (Table 9.21.1). Tropicamide (Mydracil®) has a very short half-life and should not be used to determine the cycloplegic refraction. Cyclopentolate is effective and has sufficient half-life to be the standard in pediatric ophthalmology. Phenylephrine (adrenaline), a sympathomimetic, causes mydriasis but has no significant effect on accommodation.

Accommodative ability decreases with age. Although a great deal of variability occurs in the normal levels of accommodation, children have remarkable accommodative abilities and presbyopia is rare prior to age

TABLE 9.21.1 Standard Cycloplegic Agents

Agent	Available Concentrations (%)	Maximum Effect for Cycloplegia (minutes)	Duration of Cycloplegia (hours)
Tropicamide	1, 2	15	4–6
Cyclopentolate	0.5, 1, 5	20–45	24
Homatropine	2, 5	45–60	72
Scopolamine	0.25	30–60	168 (7 days)
Atropine	0.25, 0.5, 1	120	360 (15 days)

TABLE 9.21.2 Accommodative Amplitudes at Given Ages

Age (years)	Amplitude of Accommodation (D)	Near Point When Emmetropic (cm)
20	+11.00	9.1
32	+8.00	12.5
40	+6.00	16.7
44	+4.00	25.0
48	+3.00	33.3
56	+2.00	50.0
64	+1.00	100.0

35 years. Normal values for accommodative amplitudes are given in Table 9.21.2.

**OCULAR MANIFESTATIONS**

Because accommodation is part of the near reflex, it is linked closely with convergence and pupillary miosis. Clinically, it is very difficult to separate these components, and the presence of pupillary miosis is a good indicator of accommodative effort.

Disorders of accommodation present with blurred vision at near. Patients who have latent hyperopia must use a portion of their accommodative reserve to focus at distance and may present with premature presbyopia. Mild myopia, in contrast, may delay symptoms of presbyopia.

Most disorders of accommodation are bilateral. Thus, if the patient is corrected to emmetropia, the amount of near blurring should be similar in each eye. Disorders that present as a unilateral loss of accommodation localize to the infranuclear third cranial nerve, the ciliary ganglion (Adie’s syndrome), or the effector organ (ciliary body) itself (pharmacological cycloplegia).<sup>3</sup>

**DIAGNOSIS**

Accommodation can be measured by determining the accommodative amplitude or the accommodative range.<sup>4,5</sup> In all tests, it is important that refractive error be corrected properly to put the far point at infinity and render the ocular system emmetropic at distance.

Three methods are typically used to determine accommodative amplitude:

- A small target is brought forward toward the eye until the patient reports blurring. This distance is called the *near point of accommodation*. The reciprocal of the distance at which the target blurs is the accommodative amplitude. For example, if the target blurs at 25 cm distance, the subject has +4.00 diopter (D) of accommodative amplitude.
- The Prince rule—to determine accommodative amplitude, a scaled ruler combined with a near add of +3.00 D, which puts the far point of a person with emmetropia at 33 cm. The target on the Prince rule is

brought forward until the patient reports blurring; this distance is then converted into the diopters of accommodative amplitude, taking into account the +3.00 D addition.

- A distance target and lenses of increased minus sphere to induce accommodation are used. More minus sphere is added until the subject can no longer overcome the minus lenses with accommodation. The amount of minus sphere that can be overcome represents the accommodative amplitude.

The accommodative range refers to the range of distances that can be viewed clearly by using accommodation. Typically, it is expressed without correction for emmetropia. A person with +2.00 D hyperopia with +4.00 D of accommodation would have an uncorrected accommodative range of infinity to 50 cm, whereas one with −2.00 D myopia with a similar accommodative amplitude would have an accommodative range of 50 cm–17 cm.

## DIFFERENTIAL DIAGNOSIS

The most common cause of accommodative dysfunction is presbyopia. Symptoms of bilateral, progressive blurred vision at near with eye strain, in a patient of appropriate age, are usually enough to make the diagnosis. When presbyopic symptoms or decreased accommodative amplitudes are seen in an individual younger than age 40 years, the patient most likely has latent hyperopia; a cycloplegic refraction confirms the diagnosis.

Accommodative problems also can be caused by lesions anywhere along the neuroanatomical pathway that subserves accommodation.<sup>6</sup> These, however, are relatively rare. Trauma to the parasympathetic nuclei in the midbrain, to supranuclear structures, or to the third cranial nerve can produce asthenopic symptoms. Concussion in adolescents is associated with accommodative and convergence dysfunction in approximately 50% of cases.<sup>7</sup>

Adie's tonic pupil is typically associated with decreased accommodation, which resolves over time as accommodative fibers reinnervate the pupil. Pharmacological cycloplegia also produces temporary accommodative dysfunction. Systemic medications, especially anticholinergics, can cause decreases in accommodation. A number of systemic diseases can cause either temporary or permanent loss of accommodation,<sup>6</sup> though these diseases typically do not present with loss of accommodation as a chief complaint.

Whether accommodative dysfunction occurs in otherwise healthy children is a subject of controversy in the optometry and pediatric ophthalmology literature. Some authorities believe that decreased accommodative amplitudes in children are effort related (as evidenced by lack of pupillary

constriction to an attempted near target); others believe that such an entity is real and can be treated successfully with orthoptic exercises.<sup>8,9</sup>

Increased accommodation occurs rarely. Patients with acute Horner's syndrome may notice an increased accommodative range on the affected side. An abnormally proximal near point of accommodation is caused by miotic agents, such as pilocarpine. When seen in isolation, accommodative spasm is usually a functional disorder associated with episodic esotropia, diplopia, blurred vision at distance, miosis, and an abnormal near point of accommodation. It has been reported as a persistent condition, but this is rare, and may respond to cycloplegia.<sup>10</sup> Accommodative spasm has been associated with numerous other systemic conditions, including head trauma.<sup>6</sup>

## TREATMENT

Once any latent hyperopia has been addressed, the treatment of presbyopia involves the use of plus lenses for near work either in a bifocal or as reading glasses. Several methods can be used to determine the proper addition. Most problems with reading additions result from overcorrection for the near distance. Correction to emmetropia and the use of trial frames (rather than the phoropter) to determine the proper addition yield the best results. Multifocal intraocular lenses and monovision correction are also used as treatment for presbyopia. Acquired causes of loss of accommodation can be treated similarly.

# Headache and Facial Pain

Joel M. Weinstein, Michelle Y. Wang

9.22

**Definition:** Chronic, intermittent, or episodic pain that involves the head, skull, scalp, or face.

### Key Features

- Most headaches fall into specific rubrics (e.g., migraine, tension-type headache) that involve fairly common patterns of symptoms.
- Most headaches do not reflect serious organic disease, but a thorough history is critical to identify certain red flags.

### Associated Feature

- Although usually benign, the pain from headaches can be devastating and interferes with routine activities.

## INTRODUCTION

Headache and facial pain are among the most common complaints seen in medical practice. In this chapter, a working approach to facilitate the diagnosis of patients with headache is elucidated. This requires both knowledge of various nonophthalmological disorders and a methodology with which to elicit the relevant clinical history.

### The Art and Science of Taking a Headache History

To sort out the multitude of factors that can contribute to or cause headaches, it is essential to obtain a relevant past medical history, a basic neurological review of systems, and a directed headache history (outlined in the next section and in [Box 9.22.1](#)).

### Basic Outline of the Headache History

#### *Date of Onset, Age at Onset, and Frequency of Symptoms*

The length of time that a patient has suffered from headaches is the first guidepost in differentiating benign headaches from those that signify a progressive neurological or systemic disorder. At one end of the spectrum, a pattern of long-standing intermittent headaches with headache-free intervals recurring over months to years is rarely indicative of serious intracranial or systemic pathology. Most of these patients have vascular or tension-type headaches. Conversely, the sudden onset of severe and persistent headaches in an otherwise headache-free individual, especially when accompanied by focal neurological signs or symptoms, is clearly a cause for concern. Patients experiencing their first attack of migraine may

cause confusion in this regard, however, because the initial episode may be accompanied by focal deficits (e.g., hemianopia) but not by the typical signs and symptoms that characterize most recurrent vascular headache episodes.

Some headaches develop, and perhaps progress, over weeks to months. Although most headaches in this category have a benign cause, this is the group of patients in which serious intracranial or systemic pathology should be carefully ruled out. Headaches that result from intracranial masses or increased intracranial pressure usually have an insidious onset and occur daily, and there are rarely prolonged headache-free intervals.

### Location

Tension-type headaches are often occipital in location and extend to the posterior neck and shoulders ([Fig. 9.22.1](#)). However, intracranial processes, especially in the posterior fossa, can cause a similar distribution of pain. A band-like distribution of pain, which presumably reflects occipitofrontalis tension, also is quite common in patients who have tension-type headache. Hemicranial headaches that become holocephalic are generally vascular (i.e., migrainous) in nature. Headaches of dental or sinus origin frequently cause frontal, periorbital, or malar pain.

### Duration

Persistent and unrelenting pain that lasts for days at a time rarely results from vascular or tension headaches; it should arouse suspicion of intracranial disease, sinus inflammation, cranial arteritis, or carotid dissection.

### Predisposing Factors

For a minority of patients with vascular headache syndromes, foods or allergens have been identified that precipitate headaches.<sup>1</sup> These include chocolate, red wine, oranges, and fatty foods. In other vascular headache patients, stress—or, more commonly, relief of prolonged stress—triggers a headache episode. Other triggers for vascular headache include bright lights, exercise, sexual intercourse, and alcohol.

### Preceding Symptoms

Many patients with vascular headaches have some form of premonitory symptoms that precedes their headache by as much as 24 hours or more.<sup>2</sup> This may include drowsiness, irritability, insomnia, depression, or hypomania. Unformed visual hallucinations occur in 10%–15% of migraineurs; typically, these last 10–40 minutes and are followed almost immediately by headache. It is important to differentiate the migrainous visual prodrome from the hallucinations that may occur as epileptiform phenomena in patients who have more serious intracranial disease (see later).

### Quality and Severity of Pain

Both vascular headaches and headaches that result from intracranial masses may vary widely in severity, from mild to excruciating. Pain from vascular headache starts out as a dull ache but frequently becomes pulsatile and often is described as “throbbing.” It may be alleviated by compression or massage of the external carotid artery; usually, it is exacerbated by physical activity. Cluster headaches characteristically are extremely severe. Tension-type headaches are seldom severe enough to require bed rest and rarely are described as “throbbing.” Headache from intracranial hemorrhage typically is quite severe and usually is accompanied by focal signs or other neurological symptoms.

### Accompanying Symptoms

Nausea, photophobia, phonophobia (e.g., aversion to sound, especially loud noises), and drowsiness frequently occur during acute migraine headaches and are useful in differentiating vascular from nonvascular paroxysmal headache syndromes. These symptoms also may occur in acute

#### **BOX 9.22.1 Basic Outline of the Headache History**

intracranial processes, however, which must be distinguished on the basis of other signs and symptoms. A detailed review of neurological symptoms must be elicited from all patients with headache, and this greatly aids in identifying patients who have intracranial inflammation, hemorrhage, or space-occupying lesions.

## DIFFERENTIAL DIAGNOSIS OF HEADACHE SYNDROMES

The International Headache Society (IHS) has classified headache and facial pain disorders and has provided diagnostic criteria by which various syndromes can be distinguished (a partial listing is given in [Box 9.22.2](#)). At this time, however, no specific diagnostic tests exist for the three most common headache disorders:

- Migraine.
- Tension-type headache.
- Cluster headache.

The diagnostic criteria, therefore, are highly dependent on an accurate and reliable history.

### Migraine

The IHS classification separates patients with migraine into those without focal neurological symptoms, or “aura,” preceding or accompanying the headache and those with such symptoms (subtypes 1.1 and 1.2, respectively). Subtype 1.3 describes frequent and chronic headache that could be either tension-like and/or migraine-like. Prolonged attacks or attacks that result in permanent ischemic damage to the central nervous system are defined as complications of migraine under subtype 1.4. Subtype 1.5 describes migraine-like attacks but excludes one of the diagnostic features, and this type was previously termed *migrainous disorder* and now termed *probable migraine*. Subtype 1.6 includes several well-recognized but uncommon clinical syndromes associated with migraine with or without aura. This subtype was previously noted to occur in childhood and termed

*childhood periodic syndromes* or *abdominal migraine*; however, it can occur in adulthood as well.

### Epidemiology of Migraine

Migraine has been a major public health issue, costing significant disability and medical expenses. Data from National Ambulatory Medical Care Survey/National Hospital Ambulatory Medical Care Survey showed that headache was the fifth leading cause of emergency room visits. In the United States, large-scale surveillance studies, including the National Health Interview Survey and the National Health and Nutrition Examination Survey, found that the 3-month prevalence rates of migraine ranged from 16.6% to 22.7%.<sup>3</sup> The American Migraine Prevalence and Prevention found prevalence rates of 11.7% for migraine and 4.5% for probable migraine.

Migraine is more common in women, affecting one in every four women. The prevalence is lower in children but is still substantial,<sup>4</sup> with an equal prevalence of about 3% for boys and girls at age 7 years, increasing to 15% at age 15 years. The first attack of migraine occurs before age 10 years in about 25% of patients, by age 25 years in about 65%, and by age 40 years in more than 90%.<sup>4</sup> Onset in later life does occur, however, and may be confused with transient cerebral ischemia. The criteria used to differentiate migraine equivalents in older patients from transient cerebral ischemic episodes have been discussed at length by Fisher.<sup>5</sup> Of all features, visual symptoms are the most common presentation in late-life migraine.<sup>6</sup>

No consistent relationship to ethnic group, socioeconomic status, or personality profile has been found. However, a familial predisposition for migraine clearly exists. One genetic study found a risk of 70% if both parents were affected and 45% if only one parent was affected.<sup>7</sup> The pattern of inheritance appears to be complex and multifactorial. More genetics studies are underway, which may provide more insights into the pathophysiology of migraine.<sup>8</sup>

### Clinical Features of Various Migraine Syndromes

#### Migraine Without Aura (Previously Termed Common Migraine)

The IHS published its third edition of *Classification of Headache Disorders* in 2013.<sup>9</sup> Migraine without aura is defined by the IHS as at least five attacks

### BOX 9.22.2 Partial Listing of the IHS Classification of Headaches (2013)

1. Migraine
  - 1.1 Migraine without aura
  - 1.2 Migraine with aura
    - 1.2.1 Migraine with typical aura
      - 1.2.1.1 Typical aura with headache
      - 1.2.1.2 Typical aura without headache
    - 1.2.2 Migraine with brainstem aura
    - 1.2.3 Hemiplegic migraine
    - 1.2.4 Retinal migraine
  - 1.3 Chronic migraine
  - 1.4 Complications of migraine
    - 1.4.1 Status migrainosus
    - 1.4.2 Persistent aura without infarction
    - 1.4.3 Migrainous infarction
    - 1.4.4 Migraine aura-triggered seizure
  - 1.5 Probable migraine
  - 1.6 Episodic syndromes that may be associated with migraine
2. Tension-type headache
3. Trigeminal-autonomic cephalalgias (TACs)
  - 3.1 Cluster headache
  - 3.2 Paroxysmal hemicrania
4. Other primary headache disorders
  - 4.7 Primary stabbing headache
6. Headache attributed to cranial or cervical vascular disorder
  - 6.4.1 Headache attributed to giant cell arteritis (GCA)
11. Headache or facial pain attributed to disorder of the cranium, neck, eyes, ears, nose, sinuses, teeth, mouth or other facial or cervical structure
  - 11.5 Headache attributed to disorder of the nose or paranasal sinuses
13. Painful cranial neuropathies and other facial pains
  - 13.1 Trigeminal neuralgia
  - 13.8 Paratrigeminal oculosympathetic (Raeder's) syndrome

For the complete classification, see Headache Classification Committee of the International Headache Society. The International Classification of Headache Disorders, 3rd ed. (beta version). Cephalalgia 2013 Jul;33(9):629–808.

of headache lasting 4–72 hours, which has at least two of the following characteristics: (1) unilateral, (2) pulsating, (3) moderate or severe intensity, and (4) aggravation by physical activity. The headache is associated with (1) nausea, and/or vomiting; or (2) photophobia and phonophobia. Migraine headache in children and adolescents is more commonly bilateral. Although migraine without aura is not preceded by focal neurological symptoms (by definition),<sup>10</sup> many patients notice autonomic or mood disturbances as long as 24 hours before an impending attack.<sup>2</sup> These include irritability, depression, drowsiness, and hunger (sometimes with a craving for specific foods). Other patients may experience hypomania or elation. These premonitory symptoms presumably arise in the hypothalamus; it is interesting, in this regard, that similar symptoms may be induced by certain 5-hydroxytryptamine (5-HT) antagonists.<sup>11</sup>

The headache phase of migraine without aura usually begins unilaterally, often in the periorbital area, and may or may not progress to become holocephalic. The pain may begin anywhere on the head or face. Although many migraineurs report a strong predilection for episodes to occur repeatedly on the same side, most report occasional episodes on the other side as well. Frequent episodes that involve only one side should arouse suspicion of a space-occupying lesion. The pain often is described as “throbbing,” usually builds over 1–2 hours and typically lasts 4–8 hours; however, attacks that last up to 24 hours are not uncommon. The pain usually is exacerbated by routine physical activity, such as bending or minor exertion. Nausea is a prominent feature in 80%–90% of migraineurs, but vomiting is relatively uncommon. Photophobia and phonophobia are relatively common, and most patients withdraw to a dark, quiet room and lie still during severe attacks. Drowsiness is common, and many patients find that sleep provides substantial relief.

#### Migraine With Aura (Previously Termed *Classic Migraine*)

The IHS defined migraine with aura as having at least two attacks of one or more reversible aura with at least two of the following characteristics: (1) at least one aura symptom occurring gradually over  $\geq 5$  minutes; (2) aura symptom lasting 5–60 minutes; (3) at least one aura being unilateral,

**Fig. 9.22.2 Scintillating Scotoma in Migraine With Aura.** The leading edge of the scotoma is “positive” (i.e., it consists of bright flickering imagery that obscures or replaces the normal visual field), whereas the trailing edge of the scotoma often is “negative” (i.e., it displays a relatively dark area that fully or partially obscures the visual surround). The illustration depicts a typical fortification scotoma with sharply angulated borders; many other variants of the migraine scotoma may occur (see text).

and (4) aura accompanied or followed by headache within 60 minutes. Aura symptoms are most often visual symptoms but can also be sensory, speech, motor, or brainstem symptoms.

Migraine with aura is characterized by a prodrome consisting of a completely reversible focal neurological symptom that typically lasts 15–45 minutes.<sup>7,11–13</sup> This prodrome is followed by a headache with a duration and quality similar to that of migraine without aura. The most common prodrome is, of course, the homonymous scintillating scotoma. Less frequently, the aura may consist of a hemi-sensory disturbance (paresthesia or numbness that involves one side of the body or face), hemiparesis, or dysphasia.<sup>10,12</sup> With the exception of the typical homonymous visual aura (described later), patients who have focal neurological defects require neurological consultation to differentiate migraine from more serious transient cerebral ischemia.

The most common description of the visual aura is the perception of multicolored shimmering (scintillating) lights, beginning in the paracentral area and expanding in a crescent-shaped fashion to obscure a large portion of a homonymous hemi-field of both eyes (Fig. 9.22.2). The borders of the scotoma often have jagged edges (teichopsia, or fortification scotoma, analogous to a medieval fortress). Although the leading edge of the scotoma may be “positive” (i.e., may have flickering imagery that obscures or replaces the normal visual field), the trailing edge of the scotoma is often “negative” (i.e., displays a relatively dark area that fully or partially obscures the visual surround, as illustrated in Fig. 9.22.2). Other variants include a gray, black, or colored haze; the perception of a swirling pool of water; and “television interference” or “snow.”<sup>13</sup>

It is quite common for patients who have homonymous visual loss of any cause to perceive their deficit incorrectly as monocular and ipsilateral to the visual field defect. In patients who report monocular loss, it is imperative to determine whether each eye was checked separately. In most instances, the patient’s report of a negative scotoma with both eyes open is an indication that the episode of visual loss was homonymous rather than monocular.

#### Structural Lesions That Mimic Migraine With Aura

Rarely, structural disease that involves the occipital region will mimic migraine with visual aura. In particular, arteriovenous malformations (AVMs) of the occipital lobe are examples, which may cause transient homonymous visual loss with scintillating scotoma and headache. In the vast majority of cases, however, these two syndromes may be differentiated on clinical grounds alone. In two large series on occipital AVMs,<sup>14,15</sup> none of the patients had the 15- to 20-minute visual episodes that are characteristic of classic migraine. The headaches in patients with AVMs were consistently localized to the same side. In addition, the visual phenomena often persist intermittently throughout the headache, unlike in classic migraine, in which the visual aura is usually complete before the onset of headache.

### Recurrent Painful Ophthalmoplegic Neuropathy (Previously Termed *Ophthalmoplegic Migraine*)

The IHS defined recurrent painful ophthalmoplegic neuropathy as at least two attacks of unilateral headache accompanied by ipsilateral paresis of at least one ocular motor nerve. The vast majority of patients experienced their first attack in early childhood.<sup>16</sup> Recurrent painful ophthalmoplegic neuropathy almost always involves the third cranial nerve. Rare cases of sixth cranial nerve involvement, and even rarer cases that involve the fourth cranial nerve, have been reported. It is important to exclude other reasonable causes by clinical and radiological studies.

In addition to these criteria, Daroff<sup>17</sup> pointed out that a characteristic abnormality has been demonstrated in all cases involving the third nerve in which magnetic resonance imaging (MRI) has been performed: thickening and contrast enhancement of the nerve root as it exits the midbrain. This and other clinical findings led Lance and Zagami<sup>18</sup> to postulate that recurrent painful ophthalmoplegic neuropathy is a recurrent demyelinating, inflammatory cranial neuropathy.

The headache that occurs in recurrent painful ophthalmoplegic neuropathy is not always severe. It usually begins ipsilaterally but may become bilateral; it lasts from several hours to days. Rarely, the pupil is spared. The ophthalmoplegia usually resolves completely, but residual ptosis and ophthalmoplegia may be present after repeated attacks. Resolution usually requires several weeks or, less commonly, several months.

The differential diagnosis of painful ophthalmoplegia is discussed at length in Chapter 9.16. In practice, when presented with a patient who is undergoing a first episode of pupil-involving third nerve palsy, it is almost always necessary to rule out an aneurysm or other compressive lesion via neuroimaging studies.

The etiology of recurrent painful ophthalmoplegic neuropathy is uncertain and multiple mechanisms may be involved. The evidence for these disparate, but perhaps complementary, mechanisms has been discussed at length by various authors.<sup>16-18</sup>

### Retinal Migraine

The IHS defined retinal migraine as having at least two attacks of fully reversible monocular positive and/or negative aura with at least two of the following characteristics: (1) aura spreading gradually over  $\geq 5$  minutes; (2) aura lasting 5–60 minutes; and (3) aura accompanied by or followed by headache within 60 minutes. Although most visual symptoms in migraine are hemianopic and cortical in origin, transient (rarely permanent) monocular visual loss is well documented.<sup>19-21</sup> Both optic nerve<sup>21</sup> and retinal<sup>19,20</sup> ischemic episodes have been reported in migraine. In some cases, the amaurosis may occur during, rather than before, the headache phase. Retinal vasospasm has been observed ophthalmoscopically during the attack in several patients.

There appears to be two categories of young patients who experience amaurosis fugax secondary to presumed or observed vasospasm. The first group includes individuals who have well-established migraine, with or without hemianopic auras, who develop migraine headaches associated with episodes of amaurosis fugax.<sup>19,22,23</sup> The second group consists of young patients with no history of migraine who experience episodes of amaurosis fugax.<sup>19</sup> The mechanism of visual loss in this second group is less clear, and its relationship to the dynamics of migraine is less certain than for the first group. Many of the patients in the second group have antiphospholipid antibodies or other evidence of autoimmune disturbance. Nevertheless, patients in this group, like those in the first, tend to respond well to calcium channel blockers or sometimes to aspirin.<sup>22,23</sup> It has been suggested that retinal vasomotor instability, as a result of a migraine-like mechanism, may be compounded by interference with prostacyclin release at the endothelial cell level (in some cases because of antiphospholipid antibodies).<sup>24</sup> This would account for the beneficial effect of both aspirin and calcium channel blockers. However, nonmigraine diagnoses should be excluded in all patients (young and old) who have amaurosis fugax. These diagnoses include embolic disease from the heart and carotid-ophthalmic system, hypercoagulability and hyperviscosity of various causes, and systemic vasculitides (for a detailed discussion of the differential diagnosis of amaurosis fugax, see Chapter 9.26).

### Pathogenesis of Migraine

Although the pathogenesis of migraine remains uncertain, most researchers believe that the vascular alterations are not primary but result from a complex interplay of neuronal, hormonal, hematological, biochemical, and myogenic factors. The major controversies revolve around the mechanisms by which the prodrome, aura, and headache phases are triggered by the following:

Fig. 9.22.3 Proposed Pathogenesis of Migraine.

- Primary aberrant neuronal activity.
- Various neuropeptides and vasoactive substances.
- Primary alterations in extra- and intracerebral blood flow.

Although an exhaustive discussion of migraine pathogenesis and the interplay of these mechanisms is beyond the scope of this chapter, the major theories are outlined briefly and illustrated in Fig. 9.22.3. The interested reader is referred to a thorough account in two reviews.<sup>25,26</sup>

On the basis of epidemiological evidence, there is general agreement that migraineurs have a genetically determined lower threshold for certain environmental (or internal) triggers that can initiate a peculiar cascade of vascular and neurogenic events and lead to a migraine episode. Migraineurs differ from headache-free controls in several aspects of pain control and cerebrovascular reactivity, including the following:

- Altered hypothalamic and brainstem responses to various stimuli, including dopaminergic agonists.

- Altered intra- and extracranial vascular reactivity to stress, exercise, carbon dioxide, and cold stimuli (e.g., brief headache induced by ice cream is much more common in migraineurs).
- Diminished responses at various central nervous system sites to dopaminergic agents.
- Altered platelet function, especially with regard to 5-HT (or serotonin) release.

On the basis of data from both human study and an experimental model, Lance et al.<sup>11</sup> proposed the mechanism for the development of migraine outlined here and illustrated in Fig. 9.22.3. An inherited migraine threshold renders the migraineur unusually susceptible to fluctuations in cortical or hypothalamic function (signaled by mood changes, excessive thirst, hunger, etc.). Once this threshold is reached, the following sequence of events is activated (see Fig. 9.22.3).

Brainstem nuclei, including the nucleus raphe dorsalis (NRD) and the locus ceruleus (LC), are activated by cortical and hypothalamic events. These pathways employ 5-HT and norepinephrine (NE; noradrenaline), respectively, as neurotransmitters. Stimulation of the LC causes constriction of the cortical microcirculation blood vessels via release of the neurotransmitter NE. Stimulation of the LC, NRD, or trigeminal nerve may cause dilatation of the extracranial vasculature.

Cortical ischemia produced by microvascular changes may be accompanied by spreading neuronal depression, associated with focal neurological symptoms (e.g., homonymous hemianopia). This accounts for the migrainous aura, which may occur independently of the headache.

Release of 5-HT and vasoactive peptides at nerve endings on blood vessels may induce a sterile inflammatory response, which results in pain. This response may be perpetuated by local axon reflexes or by a central reflex pathway.

Stimulation of the LC also causes release of NE from the adrenals; NE, or an unknown 5-HT-releasing factor, causes platelets to release 5-HT into the circulation. Free 5-HT causes increased sensitivity of vascular receptors, which potentiates both abnormal vascular reactivity and the painful inflammatory response.

Pain afferents from intra- and extracranial vascular structures synapse on second-order neurons in the spinal nucleus of the trigeminal nerve. Transmission at these neurons is regulated, in part, by the LC, as well as by other brainstem nuclei. Improper activity of the LC may potentiate transmission of pain impulses at these synapses.

### Treatment of Migraine With Aura and Migraine Without Aura

The management of migraine should include patient education and reassurance, avoidance of triggers, and both nonpharmacological and pharmacological therapy.<sup>27</sup> Lifestyle modifications, including regular exercise, maintaining a regular sleep pattern, and smoking cessation, are an important part of headache management. Others may find relaxation training and biofeedback helpful. Pharmacological therapy consists of acute (abortive) treatment to terminate an attack and relieve pain and preventive (prophylactic) treatment to reduce attack frequency, severity, and duration. Medication should be selected on the basis of side-effect profiles, comorbidities, and personal considerations and tailored to each patient.

Acute migraine treatment consists of nonspecific and specific agents. Nonspecific medications, such as analgesics, opioids, antiemetics, corticosteroids, and dopamine antagonists, may be able to control acute pain caused by migraine as well as other pain disorders. More specific medications, including ergotamine, dihydroergotamine (DHE), and triptans can better control migraine attacks but not pain associated with other causes. Patients should be educated to take medications at the first sign of an attack to achieve maximal therapeutic benefits. It is important to avoid medication overuse headache by limiting acute medications to <10 days per month.

Patients with mild to moderate nondebilitating migraine may be relieved by nonsteroidal anti-inflammatory drugs, nonopioid analgesics, combination aspirin-acetaminophen-caffeine, or isometheptene muate-dichloralphenazone-acetaminophen.

For patients who have more severe migraines, use of specific medications, such as triptans or DHE, is the preferred treatment.<sup>28</sup> Several triptans are available for oral use. Patients with nausea and vomiting may be given intranasal sumatriptan or zolmitriptan or subcutaneous sumatriptan. Triptans should not be used again within 24 hours or within 24 hours after the use of ergotamine. Given concern for cardiovascular risks, triptans should also not be used in patients with ischemic heart disease, Prinzmetal's angina, uncontrolled hypertension, or vertebrobasilar migraine. Most triptans should not be used in combination with monoamine oxidase

inhibitors. When triptans are used in combination with selective serotonin reuptake inhibitor, the concern for added risk of serotonin syndrome has been raised but is likely low.<sup>29</sup> Nevertheless, risks and benefits must be considered on an individual basis.

If triptans or DHE fail, parenteral ketorolac can be tried. A single dose of parenteral dexamethasone added to abortive therapy for severe migraine headache was found to be associated with a 26% reduction in recurrence rate within 72 hours.<sup>30</sup> Opioids or butalbital should only be used as the last resort.

For patients who have frequent attacks or who do not respond to acute treatment, daily treatment for prophylaxis of headache is warranted. Preventive treatment can reduce the frequency and severity of migraine attacks, improve responsiveness to acute attacks, and prevent progression to chronic migraine. Treatment is highly individualized and may be selected based on the comorbidities. The American Academy of Neurology and the American Headache Society published a guideline for episodic migraine prevention in adults.<sup>31</sup> Beta-blockers (metoprolol, propranolol, or timolol), antiepileptic drugs (divalproex sodium, sodium valproate, topiramate), and triptans (frovatriptan) are effective agents and should be offered to patients for migraine prevention. Antidepressants (amitriptyline, venlafaxine), other beta-blockers (atenolol, nadolol), and other triptans (naratriptan, zolmitriptan) are probably effective and should be considered.

Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers are possibly effective. Calcium channel blockers are frequently used, but data are conflicting. Botulinum toxin injection has been effectively used for chronic migraine.

Controversies in the treatment of migraine are thoroughly discussed in the review by Evans and Lipton.<sup>32</sup> Topics covered include prophylaxis for recurrent or chronic migraine, treatment of basilar or complicated migraine, and use of oral contraceptives in migraine.

## Tension-Type Headache

Episodic tension-type headache is the most common form of headache seen in medical practice.<sup>33</sup> Most patients describe their tension headaches as a mild to moderate "pressing" or "squeezing" sensation, or they may compare the pain to a tight band that encircles the scalp. The pain is generally nonpulsatile and almost always bilateral. It may be bifrontal, bioccipital, or "band-like." Pain radiating to the posterior neck is common, as is tightness of jaw muscles. Nausea, photophobia, and phonophobia are absent or minimal. Unlike migraine, tension headaches are not exacerbated by routine physical activity. In addition, unlike migraine, tension headaches are not preceded by the prodromal constitutional or focal neurological symptoms noted earlier.<sup>33</sup>

Tension headaches may occur as infrequently as once a year and last only 30 minutes, or they may last all day and occur daily in an unrelenting fashion. Most patients who seek medical attention for their tension headaches have episodes that occur several times weekly or monthly, punctuated by headache-free intervals. The presence of headache-free intervals helps differentiate these headaches from more serious pathological processes, also taking into account the absence of other systemic or neurological symptoms. These patients are often aware of stressful emotional triggers that precipitate their tension headaches; therefore, they can readily identify, if not control, the exacerbating factors. Depression is present in up to one third of patients who experience persistent tension headaches.<sup>33</sup> Many patients with tension headaches also have migraines, but usually they can differentiate the two types of headache on the basis of severity, duration, and associated symptoms.

There is some controversy about the role of the pericranial musculature in the production of tension headache.<sup>33</sup> Although muscle spasm and tenderness may be the result, rather than the primary cause, of chronic tension headaches in many patients, it appears that distinct myofascial trigger points can be a source of pain in some patients. The myofascial pain syndrome is characterized by reproducible pain on palpation of trigger points.<sup>33</sup> The pain generally is referred to a location somewhere along the band of taut muscle that includes the trigger point, although it may be at some distance from the trigger point itself. According to Jay,<sup>34</sup> the syndromes of tension headache, myofascial pain syndrome, and fibromyalgia represent a spectrum of severity of the same underlying disorder.

## Cluster Headache

Cluster headaches are perhaps the most painful type of "benign" headache. The pain can be so severe that some patients with this disorder report experiencing suicidal thoughts. The pain typically is unilateral and

periorbital in location and tends to occur on the same side during each attack; rarely is the opposite side involved. Unlike migraines, cluster headaches are more common in men than in women. In addition, patients with cluster headaches, unlike migraineurs, generally are hyperactive during an attack—they often pace the room or rock fitfully in a chair. Sympathetic dysfunction ipsilateral to the pain is common.<sup>35</sup> Horner's syndrome may be present during the attack, along with lacrimation, conjunctival injection, nasal congestion, rhinorrhea, and eyelid edema. Horner's syndrome may persist, especially after repeated attacks; pharmacological testing reveals a postganglionic localization. Attacks are usually shorter than in migraine and last 15–180 minutes, with an average of about 45 minutes. The attacks cluster in time; characteristically, they occur at least once daily, usually at the same time of day. Nocturnal occurrence is common, and the headache often wakes the patient from sleep. Some patients also find that attacks can be precipitated by alcohol, histamine, or nitroglycerin ingestion. As the cluster period progresses, the frequency of episodes may increase to eight per day. The cluster period typically lasts for 4–12 weeks. The patient is then asymptomatic until the next cluster period, which typically occurs a year or more later, usually at the same time of year.

The treatment of cluster headaches is highly individualized and has been reviewed at length elsewhere.<sup>35</sup> Some of the same agents used for migraine may be used for cluster headache as well and include sumatriptan for acute attacks and methysergide for short-term use (<6 months). In addition, prednisone is often effective in halting bouts of cluster headaches. For more resistant cases, lithium is often useful.

## Paroxysmal Hemicrania

Normally classified as a cluster headache variant, this unusual syndrome is characterized by multiple brief episodes of “stabbing” pain, typically in the periorbital region.<sup>36</sup> The pain usually is quite severe and lasts for 2–30 minutes. Repeated series tend to occur throughout the day, as often as 10–15 times. Episodes are accompanied by hemicranial autonomic dysfunction similar to that seen with cluster headaches. Unlike cluster headache, men and women are equally affected. The syndrome often responds to indomethacin 50 mg three times daily.

## Temporal Arteritis

Headache is the most common symptom in temporal arteritis<sup>37,38</sup>; this diagnosis should be considered in all adults age >50 years and have headache or facial pain. The headache of temporal arteritis classically is located over a branch of the superficial temporal artery and is described as a “dull ache” that persists throughout the day. It may be accompanied by tenderness of the artery and overlying scalp.<sup>37,38</sup> The artery, if severely affected, may be indurated and nonpulsatile. Many patients, however, present with a nonspecific unilateral or bilateral headache.

All patients in this age group should be asked specifically about symptoms of vasculitis and vascular insufficiency that involve the extracranial carotid circulation. These include the following:

- Presence of pain or tenderness around the temporal arteries.
- Scalp tenderness.
- Pain or fatigue with chewing (i.e., jaw or tongue claudication).
- Diplopia, which is generally thought to result from extraocular muscle ischemia rather than from cranial neuropathy.
- Transient visual loss as a result of optic nerve or retinal ischemia.

In addition, many but not all patients with temporal arteritis have symptoms of more widespread rheumatological involvement (i.e., polymyalgia rheumatica).<sup>37</sup> These symptoms may be nonspecific and include malaise and easy fatigability, weight loss, anorexia, proximal myalgias, and unexplained fevers.

A sedimentation rate should be obtained to rule out temporal arteritis in all patients a >60 years complaining of headache or facial pain, unless the pain obviously results from another cause. The test is simple, noninvasive and identifies about 90% of patients who have this disorder.<sup>37</sup> Unless otherwise contraindicated, corticosteroid therapy should be instituted, pending results of a temporal artery biopsy. A thorough discussion of the issues that surround diagnosis and therapy of temporal arteritis can be found in Chapter 9.8.

## Headache as a Result of Intracranial Processes

Ruling out intracranial pathology should be one of the primary goals of the ophthalmologist when evaluating a patient with headache. Although

### BOX 9.22.3 Warning Signs for Headaches Caused by Serious Intracranial or Systemic Pathology

New onset headache in a previously headache-free patient  
New pattern or new type of headache  
“The worst headache I’ve ever had.”  
Change in personality or mental status  
Focal neurological deficit  
Signs of meningeal irritation  
Unexplained fever  
Recent head trauma

myriad intracranial processes can cause headache, most intracranial pain is caused by inflammation or stretching of pain-sensitive structures in the dura and blood vessels. Although the complete differential diagnosis of intracranial headache is beyond the scope of this chapter, several warning signs should alert the ophthalmologist to the possibility of a serious neurological problem (Box 9.22.3):

- A change in the usual pattern of headache. An acute or subacute increase in the intensity and frequency of a well-established headache pattern should arouse suspicion, as should the onset of a new type of headache.
- Headache described as “the worst headache I’ve ever had.”
- Headache triggered by exertion, by coughing or sneezing, or by postural changes, such as bending over. These features often signal irritation or stretching of pain-sensitive intracranial structures.
- Headache accompanied by signs of meningeal irritation, such as stiff neck, nausea, vomiting, or fever.
- Headache accompanied by focal or nonfocal neurological signs (e.g., focal weakness or numbness, aphasia, impaired cognitive function, change in personality).

Negative responses to questions about these “red flags” help rule out intracranial pathology.

## DIFFERENTIAL DIAGNOSIS OF FACIAL PAIN

Facial pain may arise from a variety of structures of the face and neck, including the sinuses, nasopharynx, teeth and gums, facial muscles, orbit, middle ear, trigeminal nerve, muscles of mastication, and carotid artery and its tributaries.

### Headache Attributed to Disorders of the Nose or Paranasal Sinuses (Previously Termed *Sinus Headache*)

The diagnosis of pain that results from acute sinus inflammation is rarely difficult. A prior history of sinus inflammation or respiratory allergies is often elicited. In general, the pain is of low to moderate intensity and is present on a daily basis. The pain usually is localized to the frontal or maxillary area, and there is tenderness to percussion over the affected sinus. The pain is often worsened by bending forward and may be accentuated by blowing the nose or sneezing. Symptoms of nasal “stuffiness” are usually present, and mucopurulent drainage from the nostrils may be seen. If the nasal passages are blocked, use of a nasal decongestant can be useful diagnostically and often results in discharge. In doubtful cases, a simple plain film of the sinuses or an opinion from an otolaryngologist should be obtained.

Sphenoid mucocoeles may invade the orbital apex, resulting in ocular motility disturbances or optic neuropathy. Nasopharyngeal carcinoma has a propensity to invade the base of the skull by traveling along neural foramina.<sup>39</sup> These tumors may cause ocular motility disturbances, most commonly sixth cranial nerve palsy, facial numbness or pain, or decreased hearing as a result of closure of the eustachian tube. These tumors can be missed easily on plain films and require computed tomography (CT) or MRI for early detection.

## Orbital Inflammation and Neoplasia

Although the physical examination and differential diagnosis of orbital disease is beyond the scope of this chapter, the classic signs and symptoms should be elicited meticulously in all suspicious patients (see Chapter

12.10). Small posterior orbital masses, such as optic nerve sheath meningiomas, may cause little exophthalmos, but will be detected by careful testing of visual function, including color vision and pupillary function, and visual fields. Orbital myositis and inflammatory orbital pseudo-tumor ordinarily cause persistent unilateral pain of moderate to severe intensity, and signs of proptosis or dysmotility usually are present.

Posterior scleritis may be difficult to diagnose.<sup>40</sup> The pain is persistent, often moderately severe, and may be accentuated by eye movement. CT or MRI generally shows thickening and enhancement of the affected posterior sclera.

### Classic Trigeminal Neuralgia (Previously Termed *Tic Douloureux*)

Trigeminal neuralgia is characterized by sudden, intense jabs of pain that last only a fraction of a second to 2 minutes.<sup>41</sup> The pain generally is limited to one of the three divisions of the trigeminal nerve, with the second and third divisions involved most frequently. The pain usually is described as lancinating or “stabbing” in quality; it often recurs in a series of paroxysms that extend over several minutes. Most patients can identify a triggering activity, such as chewing, swallowing, or light touch to a part of the face, which initiates a paroxysm. Classic trigeminal neuralgia is usually caused by neurovascular compression of trigeminal nerve by the superior cerebellar artery. MRI is indicated to demonstrate the compression and rule out other secondary causes.

### Paratrigeminal Oculosympathetic (Raeder's) Syndrome

In 1924, Raeder described a series of patients with headache. The first group had episodic headaches caused by what is now known as the *cluster headache syndrome*. The second group had chronic pain in the trigeminal distribution caused by a variety of space-occupying lesions. The term “Raeder's paratrigeminal syndrome” generally should not be used, to avoid confusion between the benign cluster headache syndrome, on the one hand, and potentially lethal skull base tumors or aneurysms, on the other.

Paratrigeminal oculosympathetic syndrome is characterized by constant unilateral pain in the distribution of ophthalmic division of the trigeminal nerve and ipsilateral Horner's syndrome. All patients with suspected oculosympathetic paresis should undergo a cocaine test or apraclonidine test for confirmation and a hydroxyamphetamine test for localization (see Chapter 9.20). These tests should be followed by appropriate neuroimaging of either the base of the skull and upper neck (for postganglionic lesions) or the chest and neck (for preganglionic lesions). Trigeminal sensation should be checked in all three divisions. In patients who have facial pain and postganglionic Horner's syndrome, the clinician should be particularly aware of the signs and symptoms of dissection of the internal carotid artery.<sup>42</sup> Dysesthesia of the scalp and dysgeusia, or unpleasant taste, are common, along with postganglionic Horner's syndrome. Although spontaneous dissections occur, most middle-aged or older patients have hypertension, and most younger patients have had significant neck trauma. The condition usually is diagnosed readily with MRI (Fig. 9.22.4).

### Primary Stabbing Headache (Ice-Pick Headaches, Jabs and Jolts Syndrome)

This syndrome consists of intense stabbing pain that lasts only a few seconds and can occur in the periorbital region, forehead, or frontal area,<sup>43</sup> but extratrigeminal involvement is common. The pain can recur with irregular frequency and move from one area to another. There is no

**Fig. 9.22.4 Magnetic Resonance Imaging (MRI) of Spontaneous Carotid Dissection.** (A) T2-weighted MRI through the base of the skull demonstrates normal flow void in the right internal carotid (large arrow) and curvilinear high signal intensity in the left internal carotid (small arrow) caused by spontaneous dissection in a 52-year-old man with hypertension. (B) Magnetic resonance angiogram in the anterior oblique projection demonstrates an area of narrowing of the internal carotid artery caused by dissection (arrow) just distal to the bifurcation.

associated autonomic symptom. This type of pain is seen in about one third of migraineurs and may accompany a migraine episode or occur independently. When this type of headache occurs independently of migraine episodes, it usually is quite responsive to indomethacin.

# Tumors, Infections, Inflammations, and Neurodegenerations

9.23

Hossein G. Saadati, Alfredo A. Sadun

## Definitions:

- Tumors may compromise the function of adjacent tissues through mechanical compression.
- Infections damage tissue via direct invasion by microorganisms (bacterial, fungal, or viral) and host immunological inflammatory response.
- Inflammations reflect intrinsic responses by various tissues related to the immune system and may compromise tissue function.
- Neurodegenerations of the central nervous system often involve premature dysfunction consequent to genetic factors.

## Key Features

- Tumors, infections, and inflammations of the central nervous system may involve the meninges, the brain substance (parenchyma), or the surface of the brain (extraparenchymal).
- Neurodegenerations may be specific for certain regions of the brain (e.g., Huntington's chorea) or involve the brain diffusely (e.g., Alzheimer's disease).

## Associated Features

- Tumors may be benign or malignant and primary or metastatic.
- Inflammatory and infectious responses may be acute or chronic, according to the cadence of development.

## TUMORS

### Introduction

Brain tumors produce symptoms depending on their size, location, cell of origin, or nonspecific mechanical effects (e.g., blockage of the cerebrospinal circulation). Tumors may present with either localizing or nonlocalizing signs and symptoms. In adults with new-onset seizures, up to one third will harbor an intracranial tumor.<sup>1</sup> Nonlocalizing signs of increased intracranial pressure (papilledema and sixth nerve palsies) may be caused by an intracranial tumor.

Several tumors mimicking infections or inflammations at the base of the brain with neuro-ophthalmic symptoms will be discussed.

### Epidemiology and Pathogenesis

Tumors tend to develop in the posterior fossa in children and in the cerebral hemispheres in adults. Medulloblastomas are most common in male children age 4–8 years. Neuroblastomas, ependymomas, and papillomas of the choroid also are more common in the young.

### Ocular Manifestations

Papilledema and diplopia may be produced by intracranial tumors in any location. Tumors of the optic nerve (meningiomas or gliomas) often produce slowly progressive, painless visual loss, loss of optic nerve functions, visual field defects, and disc edema in the early stage. Eventually, optic atrophy develops. Intraorbital tumors may produce proptosis, resistance to retropulsion, orbital congestion, and diplopia.

Metastatic tumors, or malignant invasive tumors, may produce inflammation and tissue necrosis and may even simulate orbital cellulitis.

Cavernous sinus involvement may produce ophthalmoplegia with or without pain. The signs and symptoms may be quite similar to those of orbital apex syndrome. Numbness or pain in the distribution of the first division of the fifth cranial nerve is common.

Tumors near the optic chiasm, including pituitary adenoma, gliomas, meningiomas, craniopharyngiomas, tumors from the sphenoidal sinus or clivus, may involve the optic chiasm and produce a chiasmal syndrome (bitemporal visual field defects). Pituitary adenomas rarely expand suddenly when affected by necrosis and hemorrhage (pituitary apoplexy).

Tumors in the parietal and temporal lobes may involve the visual pathways and produce corresponding visual field defects. Occipital lobe tumors produce congruous visual field defects but spare visual fixation.

## Pathology

Histopathological features of tumors and immunohistochemistry are useful in the differentiation of subsets of tumor types. Biopsy specimens could be used for frozen section or permanent section or be preserved in mixed buffered aldehydes for possible electron microscopy.

## Treatment

Treatment should address the primary brain tumor, malignant cells in cerebrospinal fluid (CSF), base of the brain syndrome, paraneoplastic syndrome, or possible immune responses. At times, immunosuppressive therapy is of temporary benefit (e.g., corticosteroids for cancer-associated retinopathy or in CSF paraneoplastic disease). Radiation therapy often may be necessary.

### Course and Outcome

Responses to chemotherapy or radiation therapy are extremely variable and depend largely on the type of neoplasm. However, the long-term visual prognosis is guarded.

## INFECTIONS

### Introduction

Infections of the central nervous system (CNS) have a diverse presentation; however, most share four cardinal manifestations:

- Headache.
- Altered mental status.
- Focal neurological signs.
- Fever.

Other characteristics are important in the evaluation of affected patients (time course and natural history of the disease). *Chronic meningitis* is defined as meningitis that fails to improve or progresses over at least 4 weeks of observation.<sup>2</sup> Basilar meningitis usually runs a subacute or chronic course with moderate to high rate of mortality. Focal neurological findings are more common than in acute meningitis. Diagnosis of the causative agent is of utmost importance.

### Epidemiology and Pathogenesis

Meningitis can present with a variety of clinical syndromes. The clinical expression depends on the patient's underlying medical condition and

immune status.<sup>3</sup> *Meningococcus* infection accounts for 20% of all cases in the United States. Interestingly, serogroup B is present in 50% of such cases. In the cases of acute fulminant infectious meningitis, a severe inflammatory process occurs in the meninges, primarily in the subarachnoid spaces over the brain convexity, around the cisterns, and at the base of the brain; the reaction rarely breaks into the parenchyma. As the inflammation continues, adhesions form and interfere with CSF flow and cause meningeal fibrosis along the roots of the cranial nerves. Toxins from the infectious organism also contribute to the inflammatory process via the release of various cytokines.

## Ocular Manifestations

The systemic symptoms of fever, chills, nausea, and vomiting are often accompanied by headache, stiff neck, seizures, and cranial nerve palsies. In viral and bacterial infections, symptoms manifest acutely but are more insidious in the basilar meningitis caused by fungal infection, tuberculosis, syphilis, or other similar causes.

Basilar meningitis may produce diplopia by involving the third, fourth, and sixth cranial nerves. More rarely, an optic neuritis or chiasmatis may develop, leading to loss of vision and visual field. More often, increased intracranial pressure results in papilledema and its associated signs and symptoms.

## Diagnosis and Testing

The hallmark signs for most forms of meningitis are the meningeal signs of Kernig and Brudzinski. The key finding is an abnormal CSF analysis showing increased intracranial pressure, increased white blood cell count, cloudy CSF, increased protein, decreased sugar level, and identification of the microorganism on Gram staining with growth on the appropriate culture media. However, persistent signs and symptoms of acute meningitis with sterile CSF could be seen in patients treated partially. Negative results of Gram staining or culture and sensitivities also may reflect fungal, tuberculous, and parameningeal infections.

## Pathology

Generally, infections are identified by Gram staining or culture and sensitivities. However, on occasion, histopathology may be helpful, particularly in cases of fungal, protozoan, or atypical bacterial infections.

## Treatment

Appropriate antibiotic therapy is essential in cases of bacterial meningitis; delay can result in life-threatening consequences. It is important that the antibiotic crosses the blood–CSF barrier in sufficient concentrations to achieve therapeutic values in CSF. Maintenance of adequate fluid and electrolyte balance is important for control of cerebral edema. Administration of corticosteroids in conjunction with antibiotics has been advocated by some investigators because it is beneficial in reducing neurological sequelae in children.

## Course and Outcome

The outcome may be only minimal neurological sequelae if bacterial meningitis is treated on time and effectively. About 20%–25% of patients may experience variable sequelae ranging from minimal facial weakness and hearing loss to severe intellectual or other physical ailments, such as hemiplegia, paraplegia, seizures, cranial nerve palsies with diplopia, blindness, chronic increased intracranial pressure, syndrome of inappropriate antidiuretic hormone, and subdural effusion. In association with the human immunodeficiency virus (HIV) epidemic, infectious meningitis may become more resistant to therapy, and the process may be chronic and indolent with a poorer response to treatment.<sup>4</sup>

# INFLAMMATIONS

## Introduction

Inflammations of the brain mainly involve blood vessels with or without wall necrosis. Systemic vasculitis may be present with predominant CNS manifestations. Primary CNS vasculitis exists as well.

## Epidemiology and Pathogenesis

Vasculitis is an idiopathic disorder involving the small and medium blood vessels of the brain and spinal cord, and usually presents with multiple bilateral cortical and subcortical, either caused by ischemia or directly from the effects of inflammation. Vasculitis is most common in young adults. Granulocytes and macrophages directly destroy oligodendrocytes, neurons, and axons, either through the release of cytotoxic agents or through phagocytosis.

The specific pathogenesis varies with the type of systemic vasculitis. Polyarteritis nodosa (PAN) is rare, with a male/female ratio of 2.5:1. In systemic lupus erythematosus (SLE), most cases begin in the age range of 20–40 years, and 95% of patients are women. Giant cell arteritis (GCA) is a relatively common form of vasculitis, with a 5-year incidence as high as 24 per 100 000 in individuals of northern European ancestry who are older than 50 years. Wegener's granulomatosis is a rare entity with unknown cause and a male/female ratio of 2:1. The pathogenesis includes the evolution of necrotizing granulomas.

Sjögren's syndrome is a chronic condition with a prevalence of 2%–3% in the general population. It is caused predominantly by lymphocytic infiltration of lacrimal and salivary glands. Several cases have been reported in young adults, adolescents, and even children, although it is traditionally considered a disease of middle-aged to older women. Behçet's syndrome occurs more frequently in those of Middle Eastern, Mediterranean, or Japanese descent and has a male preponderance. Its pathogenesis remains elusive, but an association with the HLA-B5 antigen occurs in some geographical regions.

Miller–Fisher syndrome, with a mean age at onset of 43.6 years, has a male/female ratio of 2:1. Neurological symptoms are preceded by viral infection in more than 70% of cases. Vogt–Koyanagi–Harada (VKH) syndrome is a granulomatous inflammatory disorder occurring more commonly in dark-pigmented races, such as Asians, Hispanics, American Indians, and Asian Indians. It accounts for 6.8%–9.2% of all cases of uveitis in Japan. Most patients are in the second to fifth decades of life. The pathogenesis may be the selective damage of melanocytes as part of an autoimmune process.

## Ocular Manifestations

Ophthalmoplegia or optic neuropathy characterizes involvement of cranial nerves and/or posterior visual pathways with characteristic visual field defects.

The clinical manifestations vary widely as diffuse or focal neurological dysfunction. Typical symptoms of diffuse involvement include headache, seizures, confusion, hallucination, and generalized lethargy. Focal involvement may manifest as a cerebrovascular accident.

## Systemic Necrotizing Vasculitides

Systemic necrotizing vasculitides are listed in [Table 9.23.1](#). In PAN, the visual loss rarely results from retinal vasculitis, or cortical blindness. The CNS becomes involved with variable frequency, usually after the initial diagnosis of PAN. Presentation is variable and may include diffuse encephalopathy or seizures. Focal neurological deficits appear to be secondary to cerebral infarction and hemorrhage. Peripheral neuropathy (mononeuritis multiplex) is frequently the presenting manifestation; seen less commonly is a diffuse, sensorimotor type. These forms of neuropathy are attributed to ischemia or arteritis of nutrient vessels.<sup>5</sup>

In SLE, visual sensory disturbances may result from optic neuritis (inflammatory or ischemic) or papilledema. Retrochiasmatic involvement may present as transient visual phenomena (which may be mistaken for migraine) or as permanent homonymous field defects (acute or subacute). CNS involvement occurs in 35%–60% of patients with SLE. The neurological manifestations may be of diffuse or focal type.<sup>6</sup> The ocular motor pathway may be involved from the cerebral cortex to the extraocular muscles; the most common locus of involvement is a brainstem infarction.<sup>7</sup>

GCA is a common vasculitis with the most serious clinical manifestations largely being ophthalmic. One of the most devastating complications is irreversible blindness, occurring in 36% of cases. The incidence of second eye involvement is about 65% if the condition is left untreated. The most common ocular presentation is anterior ischemic optic neuropathy. Visual loss may also result from posterior optic neuropathy, severe choroidal ischemia, central retinal artery or ophthalmic artery occlusion, ischemia of anterior segment, chiasm, or visual cortex. Diplopia is related to ophthalmoplegia.

**TABLE 9.23.1 Primary Central Nervous System and Systemic Vasculitides**

Vasculitic Type	Name	Age (Years)	Central Nervous System Sign (Most Common)
Primary central nervous system	Granulomatous angiitis of the central nervous system	20–50	Headache
	Cogan's syndrome	20–30	Encephalitis
	Eale's disease	20–40	Retinal phlebitis
	Acute posterior multifocal placoid pigment epitheliopathy	15–30	Retinal inflammation
	Microangiopathy of the brain	20–40	Stroke
Systemic	Polyarteritis nodosa	40–70	Stroke
	Wegener's granulomatosis	25–50	Cranial palsy
	Giant cell arteritis	55–85	Cranial palsy
	Systemic lupus erythematosus	20–40	Organic brain
	Sjögren's syndrome	40–50	Encephalitis
	Behçet's syndrome	15–30	Cranial palsy
	Relapsing polychondritis		
	Allergic angiitis		
	Scleroderma		
	Polymyositis and dermatomyositis		
	Hypersensitivity vasculitis		
	Henoch–Schönlein purpura		
	Mixed cryoglobulinemia		
	Lymphomatoid granulomatosis		
	Takayasu's arteritis		
	Lethal midline granuloma		

In GCA, headache and pain often occur in the temples, occipital region, ear, or tongue. Jaw claudication is classic and highly specific symptom but, unfortunately, is not consistently present (found in 30% of patients). Other neurological manifestations occur in 30% of patients and include transient ischemic attacks involving the posterior circulation, infarcts of the vertebral-basilar system that produce ataxia, lateral medullary syndrome, homonymous hemianopia, dementia, otological manifestations, loss of taste, and gangrene of the tongue.<sup>8</sup>

Wegener's granulomatosis may simulate the appearance of orbital pseudo-tumor or lymphoma. Orbital involvement occurs in 20% of patients. Necrotizing scleritis and uveitis may be the initial manifestations. Involvement of the CNS occurs in 25%–50% of cases and usually presents as cranial neuropathies, hypertensive encephalopathy, and cerebral vasculitis.<sup>9,10</sup>

In Sjögren's syndrome, the cardinal ocular manifestation is dry eyes, which may result in corneal ulceration and even perforation. Optic neuropathy may occur alone but more commonly is associated with multifocal CNS disease. Presentations include acute retrobulbar optic neuritis, ischemic optic neuropathy, and insidious visual loss with optic atrophy. Cranial neuropathies may be peripheral or central. The best recognized is a trigeminal sensory neuropathy. Facial nerve involvement may compromise autonomic secretory function and exacerbate the sicca syndrome. Acute and chronic subarachnoid hemorrhages with microhemorrhages within the meninges are very common in CNS antibody-positive individuals (SS-A). Less common CNS manifestations are parkinsonism, cerebellar syndromes, and aseptic meningitis.<sup>11</sup>

In Behçet's syndrome, ocular involvement is seen in 83%–95% of men and 67%–73% of women. Bilaterality is the usual presentation, although delayed, and asymmetrical involvement of the fellow eye is common. Loss of vision as a late complication may result from chronic anterior segment inflammation, neovascular glaucoma, or occlusive vasculitis. Neovascularization, retinal detachment, and optic atrophy are common sequelae. In patients with ocular disease, 10%–30% present with meningoencephalitis, brainstem syndrome, and organic brain syndrome.<sup>12</sup>

In sarcoidosis, the most commonly affected organs are the eyes, lacrimal glands, lungs, lymph nodes, and salivary glands. Ocular manifestations include granulomatous uveitis, inflammatory glaucoma, optic neuropathy (Fig. 9.23.1), and enlarged lacrimal glands. About 5% of patients present with either central or peripheral nervous system disease within 2 years of onset. Meninges at the base of the brain are most affected; secondary infiltration of cranial nerves (37%–73%) and obstruction of CSF flow (7%) also occur. CNS parenchymal disease is common (8%–40%).

Miller–Fisher syndrome is a variant of Guillain–Barré syndrome. It consists of the triad of ataxia, ophthalmoplegia, and areflexia. The initial presentation is commonly diplopia (39%). A complete external and internal ophthalmoplegia, which may be bilateral, is seen in about 50%. Other manifestations are supranuclear gaze paresis with internuclear ophthalmoplegia, Parinaud's syndrome, and occasional facial palsy. Ataxia is

**Fig. 9.23.1 Fundus View of Optic Nerve Head in Sarcoidosis.** Note the sheathing of vessels and exudates (neuroretinitis), as well as pallid edema of the optic disc.

cerebellar in most cases. Areflexia was present in 81% of the 223 cases reviewed.<sup>13</sup>

VKH syndrome is a bilateral, diffuse, granulomatous panuveitis associated with vitiligo, alopecia, poliosis, and CNS signs. It may clinically be categorized into four phases:

- Prodrromal—characterized by headache, nausea, vertigo, fever, meningismus, and orbital pain.
- Uveitic—70% of patients present with unilateral or bilateral posterior uveitis.
- Convalescent—follows after several weeks and is characterized by depigmentation of the skin and choroid.
- Chronic recurrent—characterized by smoldering panuveitis with acute exacerbations of granulomatous anterior uveitis.

The neurological manifestations are more common during the prodromal phase. Focal neurological signs, such as cranial neuropathies, hemiparesis, aphasia, transverse myelitis, and ciliary ganglionitis, may be found but are uncommon. Lumbar puncture may reveal lymphocytic pleocytosis and elevated protein.

## Diagnosis and Testing

Angiography generally is not very sensitive for CNS vasculitis. The gold standard for such diagnosis is biopsy of the leptomeninges.<sup>14</sup>

In PAN, the common but nonspecific laboratory findings include decreased serum complement and circulating immune complexes. The diagnosis often is established by biopsy of the sural nerve or muscle. In SLE, an important laboratory test is antinuclear antibody titers (double stranded). For CNS lupus, the following laboratory tests are helpful:

- Elevated CSF immunoglobulin index or oligoclonal band.
- CSF antineuronal antibodies.
- Serum antiribosomal antibodies.

Together, these tests have a sensitivity of 100% and a specificity of 86%. Furthermore, patients who show focal presentations have evidence of antiphospholipid antibodies, abnormal results of brain magnetic resonance imaging (MRI) with multiple lesions, and peripheral vasculitis.

In GCA, the diagnosis is primarily clinical. However, more than 80% of patients have markedly elevated Westergren's erythrocyte sedimentation rate. Other helpful laboratory tests include complete blood count (for anemia), serum fibrinogen levels, C-reactive protein, and plasma activating factor. Biopsy of the temporal artery is used for definitive diagnosis.

For Wegener's granulomatosis, clinical diagnosis requires the finding of at least two of the following four criteria established by the American Academy of Rheumatology:

- Oral ulcers or purulent bloody nasal discharge.
- Abnormal chest radiographs that show nodules, fixed infiltrates, or cavities.
- Microhematuria that signals kidney involvement.
- Biopsy-proven granulomatous inflammation within the arterial wall.

**Fig. 9.23.2 Temporal Artery Almost Obliterated by Vasculitis.** In this case of giant cell arteritis, the media is filled with granulomatous infiltration (with giant cells and epithelioid cells). Also, note that the elastica has been fragmented (periodic acid–Schiff staining).

For histological diagnosis, the nasal mucosa is the best biopsy source. Another useful laboratory test is that for antineutrophilic cytoplasmic antibodies type C, a specific marker found in 90% of patients with systemic involvement.

In Sjögren's syndrome, the electroencephalography result is abnormal in more than 50% of patients. Cerebral angiography shows changes consistent with vasculitis of small to medium vessels in 20%. Brain MRI results are abnormal in about 80% of patients affected by progressive focal neurological symptoms, but these MRI changes are not distinguishable from those found in multiple sclerosis. Studies of CSF show an elevated immunoglobulin G index in 50% of cases with oligoclonal bands present. Other laboratory tests include anti-Ro (SS-A) and anti-La (SS-B) antibodies; however, a definitive diagnosis may require a salivary gland biopsy.

In Behçet's syndrome, fluorescein angiography is of major importance as an early diagnostic tool because leakage from the vessels may be found even in the absence of fundoscopic abnormalities. In sarcoidosis, the serum angiotensin-converting enzyme levels and gallium-67 scans of the head and chest are useful but biopsy of affected tissue can be diagnostic.

## Pathology

The cellular infiltrate is composed of lymphocytes, macrophages, and giant cells in all layers of the vessel wall. In PAN, a widespread panarteritis is found. The necrosis of the media and elastic membranes results, in some cases, in the formation of small aneurysms, which may thrombose or rupture. In SLE, immune complex deposits in the walls of small blood vessels; the primary damage occurs in the subendothelial connective tissues of capillaries, small arteries, veins, and endocardium. In GCA, the granulomatous inflammation results in vessel obstruction, embolism, or thrombosis (Fig. 9.23.2). The characteristic is the intimal proliferation and destruction of the internal elastic lamina.

In Wegener's granulomatosis, the granuloma formation or vasculitis involves the small arteries and veins, and a fibrinoid necrosis of the vessel wall with infiltration by neutrophils and histiocytes. In Sjögren's syndrome, the inflammatory infiltrates are predominantly lymphocytes (T cell type), macrophages, and plasma cells. Small blood vessels of the venous as well as arterial system are invariably involved. In the CNS, blood vessels within the white matter, in subcortical and periventricular locations, are mainly involved. In Behçet's syndrome, an occlusive, necrotizing, nongranulomatous vasculitis and perivasculitis are found in the uvea and retina. In sarcoidosis, noncaseating granulomas in the lacrimal glands, lymph nodes, conjunctiva nodules, or even the liver may be seen.

## Treatment

The treatment of CNS vasculitis with prednisone or cyclophosphamide may produce remission or cure.<sup>15</sup> Certain inflammations require a more specified approach. For example, in Wegener's granulomatosis, treatment involves cytotoxic therapy with cyclophosphamide and, less commonly, with methotrexate, azathioprine, and chlorambucil. The response to therapy is measured by clinical improvement and reduction of the antineutrophil

cytoplasmic antibody titer over time. Sjögren's syndrome requires pulse cyclophosphamide therapy in conjunction with corticosteroids for at least 12 months until stabilization of disease course or improvement occurs.

Treatment of sarcoidosis consists of systemic corticosteroids for several weeks. If this fails, immunosuppressive agents are used.

## Course and Outcome

The chronic course for CNS vasculitis is usually characterized by cognitive deficits and focal findings. Without treatment, patients often suffer recurrent strokes and die within a few years.<sup>15</sup> The prognosis is poor in PAN; patients die as a result of lesions in the kidneys, heart, or other viscera. Cerebral SLE may be catastrophic and generally has a poor prognosis; death may result from renal failure, infection, or CNS involvement. Wegener's granulomatosis was once regarded as fatal, but survival rates have improved with the use of cytotoxic drugs, predominantly cyclophosphamide.

The prognosis for Miller–Fisher syndrome is good, with complete recovery, on average, within 10 weeks of treatment. Secondary infections, such as pneumonia or sepsis, may cause morbidity and mortality. In VKH syndrome, the prognosis is fair, but ocular complications, including cataracts, glaucoma, and subretinal neovascular membranes, are common. The major risk for the development of complications is recurrence of the intraocular inflammation.<sup>16</sup>

## NEURODEGENERATIONS

### Introduction

Despite the specific denotation and vague negative connotation of “degeneration,” the term *neurodegeneration* continues to be used to imply a decline to a lower level of CNS function. We consider the term synonymous with *heredodegeneration*. This, as well as the older term *abiotrophy*, suggests a genetic cause for premature neuronal disease and death. Neuronal injury can be a result of metabolic, toxic, or nutritional problems; however, not surprisingly, the clinical manifestations of these two categories of disease are quite similar. Recent advances in genetics and molecular biology have elucidated inborn errors in metabolism.

### Epidemiology and Pathogenesis

Each of the neurodegenerative diseases has a different epidemiology and pathogenesis. Alzheimer's disease is the most common form of dementia (60%–70%), with a prevalence of 11% at age 65 years and 32% for those older than 80 years.<sup>17</sup> A genetic basis is strongly suspected; however, a number of environmental risk factors and even viral infections have been implicated. The pathology involves marked atrophy of the cerebral cortex. Histopathology reveals nonspecific plaques and tangles. Selective loss of large retinal ganglion cells and their axons that underlie the M-cell pathway may contribute to the visuospatial abnormalities.<sup>18,19</sup>

### Ocular Manifestations

Each neurodegenerative syndrome has its own constellations of signs and symptoms. An outline of such degenerations is given in Box 9.23.1, and a brief description of some of the more characteristic ophthalmic features is given below.

Dystonic movements are sustained contractions or spasms that may be twisting or postural and tend to increase with physical activity. In children with dystonia, involvement of the arms and legs often occurs. Dystonic tremor includes both action and postural tremor. Dystonia tends to progress from focal to segmental to generalized. In advanced cases, the affected body part remains in a fixed dystonic posture. In adults, dystonia may begin with the arms (writer's cramp), neck (torticollis), face (blepharospasm), jaw (oromandibular), tongue (lingual), or vocal cords (spastic).

Blepharospasm is a form of focal dystonia caused by contraction of the orbicularis muscles; it begins with increased blinking followed by involuntary eyelid closure.<sup>20,21</sup> In Meige's syndrome, blepharospasm is combined with oromandibular dystonia. Hemifacial spasm is considered to be a form of segmental (branchial) myoclonus.<sup>20</sup>

### Cerebellar Neurodegenerative Diseases

When the cerebellum and its connections are affected in a familial or hereditary pattern, the cardinal clinical feature is ataxia. The inherited ataxias may have an early onset; for example, Friedreich's ataxia, an autosomal recessive disorder, starts before age 30 years and presents with

**BOX 9.23.1 Neurodegenerations**

Dystonia	Drug-induced
Cerebellar	• Levodopa
Friedreich's ataxia	• Anticonvulsants
Marinesco–Sjögren syndrome	• Anticholinergics
Ramsay Hunt's syndrome	• Antipsychotics
X-Linked inherited ataxia	Metabolic and endocrine
Charcot–Marie–Tooth disease	• Chorea gravidarum
Parkinson's Disease	• Hyperthyroidism
Progressive supranuclear palsy	• Birth control pills
Shy–Drager syndrome	• Hyperglycemic nonketotic encephalopathy
Hallervorden–Spatz disease	Vascular
Chorea	• Hemichorea/hemiballismus with subthalamic nucleus lesion
	• Periarthritis nodosa
	Dementias
	• Alzheimer's disease
	• Pick's disease
	• Creutzfeldt–Jakob disease
	• Dyke–Davidoff–Masson disease
	• Charles Bonnet's disease
	Mitochondria-related diseases
	• Mitochondrial encephalopathies—DNA related
	• Leber's hereditary optic atrophy
	• Mitochondrial disease with mutations of nuclear DNA

progressive ataxia of gait, limbs, absent deep tendon reflexes, and extensor plantar responses. Patients also have dysarthria, clumsiness, and cardiopathy (91%). Less common features of Friedreich's ataxia include nystagmus (25%), pes cavus (50%), diabetes (10%–20%), deafness, and optic atrophy (25%). Posterior column disorder is seen in almost all patients. Loss of appreciation of vibration is an early sign. Results of computed tomography (CT) and MRI of the brain are usually normal, except with cerebellar atrophy. Cervical spinal cord atrophy with normal CSF is present. The course is progressive, although variability exists, and treatment is only palliative.

Ramsay Hunt's syndrome is an early-onset progressive myoclonic ataxia. The most common cause is mitochondrial encephalomyopathy. Marinesco–Sjögren syndrome is another recessive ataxia characterized by young age at onset, congenital cataracts, mental retardation, and short stature.

Autosomal dominant cerebellar ataxia (ADCA) is a form of spinocerebellar ataxia which begins during adulthood. Ataxias are categorized according to clinical characteristics and gene loci, designated as SCA1, SCA2, and so on. The most common clinical form of ADCA is SCA1, which usually begins in patients between ages 20 and 40 years, with gait ataxia, early hyperreflexia, abnormal evoked potentials, peripheral neuropathy, and pseudobulbar dysarthria. Early nystagmus and ophthalmoparesis is common. MRI shows cerebellar and brainstem atrophy, which particularly affects the pons and middle cerebellar peduncle.

Azorean disease (SCA3) presents with gait and limb ataxia, leg spasticity, dysarthria, pyramidal signs, dystonia, rigidity, amyotrophy, and facial and lingual fasciculations. The ocular manifestations are pseudo-proptosis with lid retraction, decreased blinking, and ophthalmoplegia, in which saccades are slow; also found are nystagmus and ocular dysmetria, followed by supranuclear ophthalmoplegia with spared downgaze. Ataxia SCA2 is characterized by ataxia, slow saccades without nystagmus and early loss of tendon reflexes in the arms. Other ADCAs are defined by different combinations of cerebellar ataxia and retinal degeneration.

Ataxia telangiectasia, or Louis–Bar syndrome, an autosomal recessive disorder linked to a metabolic error. Oculomotor apraxia is prominent (pseudo-oculomotor apraxia). Telangiectasias of the skin and conjunctiva are often seen.

**Parkinsonism**

The parkinsonism symptom complex is characterized by six cardinal features:

- Tremor at rest.
- Rigidity.
- Bradykinesia–hypokinesia (slow and delayed movements).
- Flexed posture.
- Loss of postural reflexes.
- Freezing phenomenon (motionlessness).

Two of these features, which must include either tremor or bradykinesia, are required for definitive diagnosis of parkinsonism. Resting tremors with the “rolling pill sign” is common. Additionally, patients have decreased attention span and visuospatial impairments. Depression develops at a rate of 2% of cases per year. Cognitive impairment may occur without memory problems.

**Progressive Supranuclear Palsy**

This is a neurodegenerative disease characterized by pseudobulbar palsy, supranuclear vertical gaze palsy (primarily downgaze), extrapyramidal rigidity, gait ataxia, and dementia. The course is evolution to bed confinement in about 5 years and death a few years later.<sup>21</sup>

**Chorea**

Choreas may be hereditary, secondary, drug-induced, metabolic, endocrine, vascular, or miscellaneous (senile, or essential).

Huntington's disease, a progressive hereditary disorder that manifests only in adult life, is characterized by chorea, personality disorder, and dementia. Sydenham's chorea is seen in children and is characterized by rapid, irregular, aimless, involuntary movements of the muscles of the limbs, face, and trunk. Patients also show emotional lability, hypotonia, and muscular weakness.

**Dementias With Eye Findings****Alzheimer's Disease**

A progressive neurological disorder may present with visual disturbances, such as anomalies of color vision, spatial contrast sensitivity disturbance, fixation instability, saccadic latency prolongation with hypometric saccades, and saccadic intrusions during smooth-pursuit eye movements.<sup>18,19</sup>

The vestibular ocular reflex is normal in most patients. Some patients may show disorders of higher cortical dysfunction, such as visual agnosia and optic ataxia. Other dementias that accompany inherited metabolic disease with eye findings include Wilson's disease, Fahr's syndrome, metachromatic leukodystrophy, mitochondrial encephalopathy with lactic acidosis and stroke-like (MELAS) syndrome, myoclonic epilepsy with ragged red fibers (MERRF) syndrome, and Hallervorden–Spatz disease.

**Charles Bonnet's Syndrome**

This is more than a type of dementia. Classically, it has been regarded as such because this condition is often an early marker for various dementias.<sup>22</sup> This syndrome involves the onset of complex and vivid visual hallucinations in the absence of clouded consciousness, medical illness, psychopathology, or intellectual impairment. Classically, the visual hallucinations may be formed or unformed and probably represent a release phenomenon in the setting of deafferentation. It may occur after a stroke or other causes of diminished vision in both eyes.

**Cerebrovascular Diseases**

In addition to the focal deficit, an acquired intellectual impairment results from multiple small brain injuries caused by stroke. Loss of memory, cognitive impairments involving attention, orientation, visuospatial abilities, calculation, and motor control are present. Cortical syndrome caused by repeated atherothrombotic or cardioembolic strokes, is characterized by obvious, focal, sensorimotor signs with abrupt onset of cognitive failure. In contrast, subcortical syndrome is notable for pseudobulbar signs, isolated pyramidal signs, depression, emotional lability, frontal behavior, mild memory impairment, disorientation, inattention, and perseveration.<sup>23</sup>

**Dementia Complex Associated With HIV**

This sequela includes several CNS problems, such as apathy, cognitive slowing, memory loss, and the more focal neurological abnormalities. The eye findings include subtle deficits of color vision and contrast sensitivity, especially in the midspatial frequencies.<sup>24</sup>

**Prion Diseases**

Prion diseases include kuru, Creutzfeldt–Jakob disease, fatal familial insomnia, and Gerstmann–Sträussler–Scheinker disease. These diseases cause rapidly progressive dementia that may include visual agnosias.<sup>25</sup>

**Diagnosis and Testing**

In Huntington's chorea, neuroimaging often shows enlarged ventricles with a butterfly appearance because of atrophy of the caudate nuclei. Prenatal testing for genetic counseling is available. The Huntington's disease gene is located near the tip of the short arm of chromosome 4.

**Fig. 9.23.3 Degenerating Axons in the Human Optic Nerve in Alzheimer's Disease.** Note several dark profiles, the largest of which has an extra myelin sheath about it (paraphenylenediamine staining, epon embedded section).

In Alzheimer's disease, aside from extensive neurological workup (psychometric testing, ophthalmological testing), a visual evoked potential test may be of diagnostic significance because these patients often show a normal-pattern visual evoked potential yet an abnormal flash visual evoked potential. Further, the electroretinograms of these patients show a lower-amplitude pattern compared with normal flash electroretinograms. Ocular motility may also be abnormal.

In prion diseases, electroencephalography shows diffuse slowing, with pseudo-periodic, biphasic, and triphasic spike and wave complexes that are time locked to myoclonic jerks. Elevated level of CSF marker, a protein designated 14-3-3 that is detected by immunoassay, is found in patients with Creutzfeldt-Jakob diseases. This test has about 96% sensitivity and specificity. However, biopsy of brain tissue remains the diagnostic gold standard.

## Pathology

The pathophysiological problem of Parkinson's disease relates to decreased dopaminergic neurotransmission in the basal ganglia with loss of dopamine receptors. The multiple causes include drug-induced, postinfection, posttraumatic, tumor-related, metabolic, hypoxic, postencephalitic, toxic, multi-infarct, and idiopathic. The pathological markers in Parkinson's disease are the so-called Lewy bodies. In Alzheimer's disease, in addition to the amyloid plaques and tangles in the cerebral hemispheres, there is degeneration of retinal ganglion cells and their axons (Figs. 9.23.3 and 9.23.4). This can also be detected by optical coherence tomography for retinal nerve fiber layer thickness.<sup>26</sup>

## Treatment

Stereotaxic thalamotomy may be useful in unilateral dystonia, but bilateral ablations carry a 20% risk of dysarthria.

Medical treatment of hemifacial spasm has been attempted but botulinum toxin injection has been proven effective though multiple reinjection is necessary. Cerebellar neurodegenerative diseases with paroxysmal (or periodic) cerebellar ataxia may be amenable to treatment with acetazolamide in doses of 250–1000 mg/day, which reduces or abolishes the attacks.

In Parkinson's disease, treatment options include dopamine precursors, carbidopa, dopamine agonist, dopamine releasers, anticholinergics, antidepressants, muscle relaxants, and surgery by using such techniques as thalamotomy, pallidotomy, subthalamic stimulation, or implants of embryonic tissues. Levodopa is the most widely used drug but the response is variable, and after 5 years of therapy, up to 75% of patients have serious complications.<sup>27</sup>

**Fig. 9.23.4 Electron Microscopy of the Optic Nerve in Alzheimer's Disease.** Demonstrated are degenerating axons (D) and glial cells with lipofuscin (L), part of the process of degeneration. Normal myelinated axons (N) are also seen.

Huntington's chorea may be treated with tricyclic antidepressants and antipsychotics.<sup>1</sup> No specific treatment exists for Sydenham's chorea, but sedatives and antidopaminergic drugs may be used.

Cholinesterase inhibitors have been used for treatment of cognitive symptoms of Alzheimer's disease with minimal success. Currently, no treatment for prion diseases exists; care must be taken to avoid iatrogenic spread from organ donation or accidental inoculation.

## Course and Outcome

Most neurodegenerative diseases have a long and relentless downward course. However, in many cases, the process may proceed very slowly. In Parkinson's disease the initial response to therapy is often excellent and may last 5–10 years. For hemifacial spasm or blepharospasm, injections of botulinum toxin show excellent control of the disorder.

# Urgent Neuro-Ophthalmic Disorders

9.24

Peter A. Quiros

**Definition:** Neuro-ophthalmic emergencies are vision-threatening and sometimes life-threatening conditions, requiring prompt diagnosis and management.

## Key Features

- Giant cell arteritis typically causes generalized symptoms, such as jaw claudication, scalp tenderness, headaches, myalgias, fatigue, and weight loss, along with visual loss.
- The majority of intracranial aneurysms arise at the levels of carotid artery, posterior communicating artery, ophthalmic artery, and the cavernous sinus.
- Cavernous sinus thrombosis usually causes eye pain, proptosis, and multiple cranial nerve palsies.
- Orbital apex syndrome shares many similar features as cavernous sinus thrombosis, with the addition of optic nerve signs.
- Painful ophthalmoplegia and vision loss are key features of pituitary apoplexy.

## INTRODUCTION

There are few true ophthalmological emergencies. Although rare, the outcomes of neuro-ophthalmic emergencies<sup>1,2</sup> can be associated with high morbidity and even mortality. The ocular manifestations of neuro-ophthalmic emergencies are but portents of more dangerous central nervous system or systemic pathology. The vision-threatening and potentially life-threatening nature of these disorders requires prompt recognition and diagnosis on the physician's part. A delay of even a few hours could result in a dire outcome.

There are five neuro-ophthalmic emergencies:

- Giant cell arteritis (GCA).
- Orbital apex syndrome.
- Intracranial aneurysm.
- Cavernous sinus thrombosis.
- Pituitary apoplexy.

These may be grouped together by initial symptoms into three categories, for ease of diagnosis:

- Entities resulting in vision loss—GCA.
- Those causing ophthalmoplegia—cavernous sinus thrombosis and intracranial aneurysm.
- Those causing both vision loss and ophthalmoplegia—orbital apex syndrome and pituitary apoplexy.

## EPIDEMIOLOGY AND PATHOGENESIS

### Giant Cell Arteritis

The incidence of GCA (in the United States) is approximately 1 in 150 000 per annum in patients age greater than 60 years.<sup>3</sup> The incidence increases sharply with age and can be as high as 44 per 100 000 among patients in their 90s.<sup>3</sup> The disease occurs three times as often in women as in men.<sup>3</sup> Caucasians are affected much more often than Blacks and Hispanics.<sup>2,3,5</sup> The mean age of onset is the seventh decade.<sup>5</sup>

GCA is a systemic disease that affects primarily medium-sized to large-sized arteries, particularly the temporal, ophthalmic, and short

posterior ciliary arteries.<sup>6</sup> Segments of these latter vessels become occluded, which leads to choroidal ischemia or ischemic optic neuropathy.<sup>7</sup> The arterial thrombosis of GCA may be demonstrated by delayed choroidal and disc filling on fluorescein angiography.<sup>8</sup>

### Aneurysm

The incidence of intracranial saccular aneurysms is approximately 9 per 100 000. The incidence of rupture of asymptomatic aneurysms increases with age, peaking during the sixth and seventh decades. They are somewhat more frequent in women than in men.<sup>9</sup> The vast majority of intracranial aneurysms arise from the carotid artery's main trunk (40%), at the level of the posterior communicating (PCOM) artery, the ophthalmic artery, and the cavernous sinus.<sup>10,11</sup> Rupture of PCOM artery aneurysms has been reported to be as high as 85%.<sup>12</sup> In addition, the PCOM artery is, by far, the most frequent location to cause a third nerve palsy prior to rupture.<sup>13</sup>

PCOM artery aneurysms generally cause pupil-involving third cranial nerve palsies. These occur either as a result of subarachnoid hemorrhage or by external compression of the third cranial nerve caused by aneurysmal expansion prior to rupture.<sup>14</sup>

### Cavernous Sinus Thrombosis

The incidence of cavernous sinus thrombosis (CST), which is a rare disorder, has not been estimated. It may be classified as septic or aseptic, the latter being the rarer of the two forms. The mortality from septic CST was nearly 100% in the preantibiotic era. Although now lower, the mortality rate remains at about 30%.<sup>4</sup>

Most septic thromboses of the cavernous sinus arise from the sphenoid or ethmoid sinuses. Dental infections, facial cellulitis, and otitis rarely lead to CST because of the advent of antibiotics.<sup>4</sup> Acute infections of the sinuses are usually caused by Gram-positive bacteria, whereas chronic infections are more often associated with Gram-negative bacteria and fungi.

Aseptic thrombosis of the cavernous sinus is associated with conditions that lead to venous thrombosis. These may include polycythemias, sickle cell disease (vasculidities), trauma, neurosurgery, pregnancy, and oral contraceptive use.

### Orbital Apex Syndrome

Less than 1% of all orbital cellulites result in an orbital apex syndrome.<sup>15</sup> However, over 50% of these occurs in patients with diabetes mellitus.<sup>16</sup> In these patients, rhinocerebral mucormycosis is, by far, the most frequent cause of orbital apex syndrome.

Even though ketoacidosis is not always present,<sup>17,18</sup> it is the most important risk factor.<sup>19</sup> Studies have demonstrated a lack of inhibitory activity against *Rhizopus* in serum from patients with ketoacidosis. It appears that this inhibitory activity is restored with correction of the acidosis.

### Pituitary Apoplexy

This life-threatening condition is rare and its incidence is difficult to establish. It is thought to occur in 0.6%–9.1% of all surgically managed cases of pituitary adenoma.<sup>20</sup>

The age range is broad, ranging from the first decade to the ninth decade.<sup>20</sup> One study estimated the peak incidence to occur during the fifth decade.<sup>21</sup> There appears to be no gender predominance.

Pituitary apoplexy occurs with sudden enlargement of a tumorous pituitary gland, usually caused by adenoma. The sudden enlargement damages surrounding structures, such as the optic chiasm and the hypothalamus.

Rapid expansion into the cavernous sinus is also not uncommon. The expansion may be caused by hemorrhage or infarction. Precipitating factors include reduced blood flow as in hypotension; stimulation of the gland in increased estrogen states, such as pregnancy; anticoagulation; and increased blood flow.<sup>21</sup>

## OCULAR MANIFESTATIONS

### Giant Cell Arteritis

Sudden visual loss is, by far, the most common manifestation of GCA, occurring in approximately 50% of these patients.<sup>22</sup> Vision loss occurs overwhelmingly as a result of arteritic anterior ischemic optic neuropathy. The permanent vision loss often is preceded by transient loss of vision, such as amaurosis fugax.<sup>23</sup>

Other causes of vision loss also associated with GCA, although occurring less frequently, include central retinal artery occlusion, choroidal ischemia, and posterior ischemic optic neuropathy. GCA should be suspected in the older patient who has central retinal artery occlusion but no history of valvular disorders or visible emboli.<sup>24</sup>

Even though vision loss is the primary ophthalmic problem found in GCA, patients may also experience diplopia. This problem may occur as a result of infarction of the extraocular muscles, their associated cranial nerves, or the brainstem nuclei. In fact, GCA may cause a greater stroke syndrome.

### Aneurysm

Ophthalmic manifestations are determined by the position of the aneurysm. These may range from vision loss resulting from ophthalmic artery aneurysms, cortical blindness resulting from basilar aneurysms, or ophthalmoplegia resulting from aneurysms of the circle of Willis or the cavernous sinus. The most common manifestation, however, is ophthalmoplegia.

Patients will have complete unilateral ptosis. Upon lifting the lid, the examiner will find an abducted eye that cannot adduct, infraduct, or supraduct. These patients usually have 1–2 mm of proptosis. This phenomenon is thought to result from laxity of the palsied musculature and not from aneurysmal displacement. Anisocoria is usually present as a result of disruption of the parasympathetic fibers that travel on the outside of the nerve. The anisocoria will be accentuated in bright light. That is, the pupil will appear dilated and unable to constrict in bright light.

Suspicion of intracranial aneurysm should be raised in all patients without diabetes but who have third cranial nerve palsies, especially those with pupillary involvement.

### Cavernous Sinus Thrombosis

In patients with septic CST, a host of ocular abnormalities will manifest. Those with infections entering the cavernous sinus anteriorly usually will have eye pain, orbital congestion, proptosis, adnexal edema, ptosis, and ophthalmoplegia. The ophthalmoplegia may involve the third, fourth, and sixth cranial nerves. In addition, there may also be involvement of the first and second branches of the trigeminal nerve.

Symptoms are initially unilateral but often become bilateral as the infection and thrombosis spread to the contralateral side through the circular sinus. This sinus connects the right and left cavernous sinuses posteriorly. In addition, these patients are usually febrile. Nausea, vomiting, and somnolence are not uncommon.

### Orbital Apex Syndrome

In patients with an orbital apex syndrome, complete ophthalmoplegia, ptosis, decreased corneal sensation, and vision loss are manifested. Unlike CST, the vision loss is present early on. Patients usually develop optic nerve signs, such as a relative afferent pupillary defect. There is little adnexal edema and orbital congestion, which are present in the early stages but develop as the disease progresses. Proptosis is often present, but patients do not always complain of pain.

Eschars rarely are seen initially but usually develop around the orbit if the disease goes untreated (Fig. 9.24.1).

### Pituitary Apoplexy

Patients usually suffer painful ophthalmoplegia and vision loss. Damage to the visual pathways occurs most frequently at the level of the chiasm.

**Fig. 9.24.1** (A) Patient with mucormycosis of the right orbit, resulting in an orbital apex syndrome. (B) Axial view from orbital magnetic resonance imaging demonstrating mucormycosis of the ethmoid sinuses with extension into orbit.

Therefore, visual field defects are common. Vision loss is variable, however, and may not always produce a relative afferent pupillary defect. The degree of ophthalmoplegia may also be variable and asymmetrical, depending on the extent of involvement of each cavernous sinus.

## DIAGNOSIS AND ANCILLARY TESTING

### Giant Cell Arteritis

The diagnosis of temporal arteritis is based on clinical signs and symptoms. Laboratory findings are helpful, and temporal artery biopsy is the confirmatory gold standard.

Systemic review results in older patients with vision loss and/or transient vision loss are usually positive. Therefore, a thorough review of systems for GCA should be performed. A diagnosis can be arrived at with great certainty if several systems show positive results for symptoms.<sup>25</sup>

Most patients complain of headache, usually unilateral headache. In addition, there is usually scalp tenderness, as well as tenderness over the affected artery. Jaw claudication is often present. Although its absence does not rule out GCA, this sign is quite characteristic of GCA, as it is seen rarely in other disorders. Finally, myalgias, fatigue, weight loss, and decreased appetite are seen frequently. Positive findings in three or more systems in the older patient should raise a high level of suspicion.

Laboratory testing usually consists of erythrocyte sedimentation rate (ESR), C-reactive protein (CRP) level, and complete blood count. The ESR and CRP level usually are elevated markedly. The ESR should be adjusted for age and gender. The upper limit of normal is considered to be age divided by two in men and age plus 20 divided by two in women.<sup>26</sup>

The complete blood count often will reveal a normocytic anemia as well as thrombocytosis.<sup>27</sup>

Temporal artery biopsy is the gold standard for diagnosis. A 2-cm segment of temporal artery should be obtained and several sections

sampled because “skip lesions” may occur; that is, sections of the affected artery may be interspersed with nonaffected sections. A single negative biopsy meeting the above criteria is usually enough to rule out GCA. However, despite low statistical yield,<sup>28</sup> if suspicion is high, a second biopsy may be performed, given that a missed diagnosis would result in dire consequences.

## Aneurysm

Frontal head pain is usually present in both ruptured and unruptured aneurysms. In an unruptured aneurysm, the pain is referred from the adjacent tentorium. Like the eye and the forehead, the tentorium is supplied by the first branch of the trigeminal nerve. A pupil-involving oculomotor nerve palsy is nearly invariably present. If such is the case, the aneurysm should be detectable by magnetic resonance angiography (MRA) or spiral computed tomography angiography (CTA).<sup>29</sup> These modalities, however, may miss intracranial aneurysms of 3 mm or less.<sup>30,31</sup> Therefore, digital subtraction cerebral angiography remains the gold standard. A saccular aneurysm of 4 mm or greater usually is seen at the junction of the internal carotid and the posterior communicating arteries (Fig. 9.24.2).

## Cavernous Sinus Thrombosis and Orbital Apex Syndrome

Apart from the ocular signs that distinguish these two entities, neuroimaging is necessary to make the diagnosis. Orbital CT without contrast and magnetic resonance imaging (MRI) with fat suppression will locate the site of involvement. In the case of orbital MRI, fat suppression is necessary to visualize involved orbital structures. The “noise” created by the fat may mask inflammation otherwise. Sinus disease is nearly always present.<sup>32</sup> In fact, orbital apex syndrome rarely occurs without adjacent ethmoid sinusitis. Sphenoid and maxillary sinus disease is also common. In either case, contrast-enhanced scans should be ordered with coronal and axial views that extend as far back as the posterior and inferior cavernous sinus.

## Pituitary Apoplexy

In addition to ocular manifestations, most patients exhibit meningeal irritation. Following the apoplexy, hypofunction of the gland is common.<sup>33</sup> Patients may, therefore, exhibit irregular menses, decreased libido, hyponatremia, hypothyroidism, or hypercortisolism.

MRI is the gold standard for neuroimaging because it will delineate both the tumor and any hemorrhage (Fig. 9.24.3). It is much more sensitive than CT.<sup>34</sup>

## DIFFERENTIAL DIAGNOSIS

### Giant Cell Arteritis

The differential of GCA is extensive. GCA is confused often with nonarteritic anterior ischemic optic neuropathy. Patients with nonarteritic ischemic optic neuropathy tend to be younger, have less severe vision loss, and have a negative review of systems as well as normal laboratory test results.

The differential may also include the following:

- Inflammatory optic neuritis—patients, usually in their 20s and 30s, have pain with eye movements, optic nerve swelling, and a negative review of systems.
- Compressive tumor—very slowly progressive vision loss, negative review of systems.
- Diabetic papillophlebitis—younger patients with diabetes, optic nerve swelling with hemorrhages, negative review of systems, mildly elevated ESR.
- Central retinal artery or vein occlusion.

## Aneurysm

If angiography findings are negative, the following entities may produce a similar clinical picture:

- Microvascular or ischemic lesions—patients usually have diabetes; pupil nearly always spared.
- Epidural or subdural hematoma—a history of trauma in most cases, mental status changes common.

**Fig. 9.24.2** (A) Digital subtraction angiography (DSA) scan of PCOM artery aneurysm resulting in third nerve palsy. (B) DSA scan of the same aneurysm after endovascular coiling.

- Meningitis or encephalitis—fever and nuchal rigidity, often accompanied by mental status changes and seizures.
- Hypertensive crisis—flame-shaped retinal hemorrhages usually present, as well as optic nerve edema.
- Migraine—a relapsing and remitting course often accompanied by nausea, photophobia, visual auras, and transient hemiplegia, ophthalmoplegia, or ataxia.

## Cavernous Sinus Thrombosis and Orbital Apex Syndrome

These entities have similar differential diagnoses because most problems arise from adjacent structures.

- Tolosa–Hunt syndrome—otherwise healthy patients, severe pain, vision loss rare, inflammatory “pseudo-tumor” seen on neuroimaging.
- Arteriovenous fistula—often with antecedent trauma, bruit may be auscultated, arterialized conjunctival vessels.

**Fig. 9.24.3** (A) Axial magnetic resonance imaging (MRI) view of enlarged apoplectic pituitary gland involving chiasm. (B) Sagittal MRI view from the same patient.

- Thyroid eye disease—rarely seen without lid retraction and lid lag, positive forced ductions, thickened extraocular muscles on CT scan with little to no sinus disease.

### Pituitary Apoplexy

Intracranial aneurysm, both expanding and ruptured, should be considered if MRI fails to reveal pituitary hemorrhage. MRA should then be performed.

## PATHOLOGY

### Giant Cell Arteritis

Biopsy specimens will reveal an overwhelming inflammatory mononuclear cellular infiltrate. There is destruction of the internal elastic lamina and necrosis of the media is seen often. Vessel lumens often are completely occluded. Multinucleated giant cells may be present (Fig. 9.24.4) but disappear within days after corticosteroid therapy is initiated.

**Fig. 9.24.4** (A) Temporal artery biopsy positive for giant cell arteritis. Note destruction of elastic lamina and almost complete luminal occlusion. (B) Normal temporal artery specimen.

### Aneurysm

Histologically, aneurysmal vessels exhibit markedly thinned media and adventitia. There is generalized disruption of the internal elastic lamina, with areas of thinning, fragmentation, and even absence. Some investigators have found a deficiency or defect in type III collagen formation, as well as a decrease in the ratio of type III to type I collagen.<sup>35</sup>

### Cavernous Sinus Thrombosis and Orbital Apex Syndrome

Sinus specimens often will reveal infectious organisms. Bacterial Gram staining should be performed to ascertain the presence of Gram-positive or Gram-negative bacteria, or both. In addition, staining with India ink and special stains for fungi should be performed to evaluate for mucormycosis. Nonseptate, large, branching hyphae that stain easily with hematoxylin and eosin are indicative of *Mucor* and *Rhizopus* species.

### Pituitary Apoplexy

This condition is marked by pituitary hemorrhage, often accompanied by necrosis, and thrombosis. Most specimens have a high degree of necrosis, making cell type identification difficult. One study, however, found null cells to be the most frequent (61%), followed by somatotroph (17%), corticotroph (11%), lactotroph (5.5%), and gonadotroph (5.5%).<sup>36</sup>

## TREATMENT

### Giant Cell Arteritis

The well-accepted management for GCA is systemic corticosteroids. Generally, the ophthalmic literature favors higher doses than the

rheumatological literature. There is no clear agreement on starting dosage.<sup>37</sup> Neuro-ophthalmologists usually start at dosages of 80–100 mg of oral methylprednisolone daily. Rheumatologists may advocate lower dosages of 40–60 mg daily. Some clinicians employ initial intravenous corticosteroid therapy. Retrospective series have indicated increased likelihood of improvement in vision in those managed initially with intravenous corticosteroids.<sup>38</sup>

ESR as a therapeutic endpoint should be tested every 4–6 weeks and therapy titrated accordingly. There is general consensus that the duration of therapy should extend for many months, often up to 1–2 years, and that the use of interleukin-6 inhibitors may help decrease the length of corticosteroid therapy.

## Aneurysm

Management of unruptured intracranial aneurysms depends, in part, on their size and position, as well as the age and health of the patient. Unruptured aneurysms may be managed via a direct or “open” surgical approach or with an endovascular approach.

The direct surgical approach aims to apply metal clips at the base of the aneurysm to close it off. This approach is quite successful but poses the same risks associated with open craniotomy. Damage to adjacent structures (oculomotor nerve) may occur.

The endovascular approach uses catheters to introduce balloons or thromboembolic coils into the aneurysm, thereby mechanically occluding it or thrombosing it. This approach carries a lower risk of mortality and morbidity but can be complicated by incomplete closure of the aneurysm or displacement of the endovascular balloon, as well as rupture caused by catheter penetration of the thin aneurysm wall.

## Cavernous Sinus Thrombosis and Orbital Apex Syndrome

Septic thrombosis of the cavernous sinus is usually managed with a combination of antibiotics and anticoagulation. Corticosteroids may also play a role in reducing inflammation. If sinus disease is present, debridement of the sinuses should also take place. If there is clinical evidence or suspicion of *Mucor*, treatment with amphotericin B should be initiated. Correction of underlying metabolic acidosis greatly increases the chances of survival.<sup>15</sup>

Orbital apex syndrome is managed in much the same way, except that in cases of *Mucor*, sinus exenteration as well as orbital exenteration may be necessary to improve survival.

Aseptic thrombosis of the cavernous sinus is managed primarily by managing the underlying condition. Adjuvant anticoagulation may stop the spread of thrombosis.<sup>39</sup>

## Pituitary Apoplexy

Most patients are managed with decompression of the sella transsphenoidally. In general, these patients have a neuro-ophthalmic abnormality prompting surgery. Some groups advocate the use of bromocriptine in cases with little or no neuro-ophthalmic deficit.

Supplementation of pituitary hormones is often necessary for prolonged periods after the apoplectic event.

## COURSE AND OUTCOMES

### Giant Cell Arteritis

The primary goal of therapy is to avert vision loss in the fellow eye. Restoration of vision in the affected eye is rare. However, if left untreated, nearly 90% of patients will suffer vision loss in the fellow eye.<sup>40</sup>

## Aneurysm

The results of surgery on unruptured aneurysms are excellent. Mortality rates with these procedures are as low as 1%–5%.<sup>41</sup> Morbidity is somewhat higher at 10%–15%, which usually manifests in the form of incomplete recovery of oculomotor nerve function or aberrant regeneration.

## Cavernous Sinus Thrombosis

The mortality rate for patients with septic cavernous sinus thrombosis is about 30%. Morbidity is very high. Nearly all survivors have some neurological deficit. These usually result from damage to the cranial nerves of the cavernous sinus. Therefore, ophthalmoplegias, sensory neuropathies, and even retinal vein or artery occlusions may be seen.

Aseptic thrombosis has a much lower mortality compared with septic thrombosis. Morbidity, nonetheless, remains high, with damage to the intracavernous cranial nerves being common.

## Orbital Apex Syndrome

The mortality from *Mucor*-induced orbital apex syndrome is reported to be between 46% and 52%<sup>42</sup> despite amphotericin B therapy. Morbidity remains high because many patients require exenteration of the sinuses and orbit. Permanent neurological deficits are common.

## Pituitary Apoplexy

Surgical decompression of the sella appears to have good neuro-ophthalmic outcomes. Improvements in visual acuity, field deficits, and ophthalmoplegia have been reported to be as high as 76%–91%.<sup>36</sup> Endocrine abnormalities, however, have remained high, with 43%–58% requiring some form of hormonal supplementation. Mortality with surgical management has remained low.

# Trauma, Drugs, and Toxins

Deborah I. Friedman, Luis J. Mejico

9.25

**Definition:** Visual abnormalities caused by brain dysfunction and injury resulting from extrinsic damage by head trauma or exposure to medications, hallucinogens, or toxins.

### Key Features

- Motility disorders, saccadic abnormalities, nystagmus, convergence insufficiency.
- Visual perceptual-motor dysfunction.
- Positive visual phenomena.
- Formed and unformed visual hallucinations.
- Dyschromatopsia.
- Visual field defects.
- Blurred vision or visual loss.
- Cerebral (cortical) blindness.

### Associated Features

- Headaches.
- Short-term memory loss.
- Impaired concentration.
- Behavioral changes.
- Other physical neurological deficits.

## TRAUMA AND THE BRAIN

### Introduction

Visual abnormalities that follow closed head trauma occur commonly and can involve any part of the visual pathway. Prompt recognition and treatment of these conditions enhance the potential for the patient's rehabilitation.

### Epidemiology and Pathogenesis

Head trauma is an important public health problem. Approximately 900 000 patients are hospitalized yearly in the United States for the consequences of closed head trauma. The most common cause of head injury in the United States is motor vehicle accident, and the severity of head injury is correlated directly with the lack of proper seatbelt and helmet use.<sup>1</sup> Of all persons injured in motor vehicle accidents, 70% incur head injuries. Men are injured twice as frequently as women, and alcohol is a significant contributing factor in men. About one half of all patients are age 15–34 years. Assault, including child and spousal abuse, accidents in the home or at the workplace, and sports injuries contribute to traumatic brain injury (TBI).

Unfortunately, few studies characterize the incidence of the visual sequelae of head trauma. After a brain injury, the visual system often is not evaluated comprehensively. This may reflect the lack of articulated complaints from patients with head injury, either because of lack of subjective experience or because of reduced cognition. Family members or rehabilitative personnel often identify the deficits and bring the patients' visual problems to medical attention. In one report, 50%–65% of patients who attended a rehabilitation facility had experienced visual disturbances after TBI.<sup>2</sup> No apparent correlation exists between the severity of the trauma and the presence of visual disorders. Indeed, a study of acute mild TBI in a pediatric trauma center emergency department found photophobia and blurred or double vision in 15%–39% of children.<sup>3</sup>

### Ocular Manifestations

Visual deficits after head injury may be monocular or binocular (Box 9.25.1). Cortical injury causes changes in refraction, saccades, and other sensory-motor relationships. The most common visual complaint after head trauma is blurred vision because of convergence insufficiency. Patients who have convergence insufficiency also may have difficulty reading, diplopia at near, eye strain, tearing, photosensitivity, and headaches. Control of saccadic eye movements can be disrupted after damage to either brain hemisphere. Esophoria and exotropia are common sequelae of head trauma. Binocular single vision may be lost after a head injury, with the breakdown of a latent phoria or loss of the normal physiological fusion of the image presented to each eye. Visual field defects after closed head trauma are not uncommon. In one report, tunnel fields that suggested functional visual loss were found most frequently and were associated with posttraumatic migraine in about half the cases.<sup>1</sup> Other visual field defects include optic nerve-related scotomata, quadrantanopia, homonymous hemianopia, bitemporal hemianopia, and cerebral blindness.

Patients who have injury to the nondominant parietal, temporal, and occipital areas may exhibit visual attention problems as well as difficulty with spatial orientation and visual recognition. Visual cognition may be disrupted after head trauma, which results in difficulty judging the spatial properties of objects and impaired mental manipulation of three-dimensional images. When spatial organization and constructive abilities are impaired, the frontal lobe is provided with inadequate feedback for the execution of motor movements. Nondominant hemisphere injury often causes impaired comprehension of visual images, which may be expressed by the patient as inability to read, despite excellent visual acuity. Words may appear to run together on the printed page. Trauma to the optic chiasm simulates a pituitary region tumor, with bitemporal hemianopia and see-saw nystagmus. Damage to the brainstem structures leads to pupillary asymmetry or irregularity, ocular motor nerve paresis, unilateral and bilateral internuclear ophthalmoplegia, skew deviation, dorsal midbrain syndrome, and nystagmus.<sup>1</sup> Saccadic deficits may occur, including failure to initiate contralateral saccades, prolonged saccadic latency, decreased saccadic accuracy toward a hemianopic field, and a tendency for the patient to be distracted by peripheral stimuli.<sup>4</sup>

### Diagnosis and Ancillary Testing

Visual complaints after head injury vary widely. The ophthalmological examination often reveals a treatable problem. However, patients may be difficult to examine because of cognitive and communication disorders.

#### BOX 9.25.1 Visual Symptoms and Signs Associated With Head Trauma

Symptoms	Signs
Blurred or decreased vision	Convergence insufficiency
Diplopia	Abnormal saccades
Difficulty reading	Oculomotor dysfunction
Photophobia	Accommodative disorders
Visual hallucinations	Fixation instability
Oscillopsia	Nystagmus
Phosphenes	Lagophthalmos
Visual field defects	
Visual perceptual-motor dysfunction	
• impaired spatial relationships	
• right-left discrimination problems	
Visual cognition deficits	
Visual inattention	

Multiple examinations may be needed to fully assess a patient with brain injury. A complete assessment may include evaluation of the eye, refraction, and examination of ocular motility, accommodation, vergence, stereopsis, visual perception, and visual fields.<sup>5</sup> The diagnosis of convergence insufficiency is made on the basis of measurement of the convergence fusional reserves. The near point of convergence alone is an unreliable measure. Skull radiographs have limited usefulness, as they show only bony pathology. Computed tomography is most useful to demonstrate skull base fractures and acute bleeding, whereas magnetic resonance imaging (MRI) shows the soft tissues and brainstem with greater clarity.<sup>6</sup>

## Differential Diagnosis

When there is a temporal association between the patient's symptoms and the head injury, a causal association is presumed. However, minor head trauma may draw attention to visual deficits from other causes that had been unrecognized previously. Patients who have homonymous or bitemporal visual field defects after trauma require neuroimaging studies to exclude a hemorrhage, tumor, stroke, or vascular malformation. Patients who seek compensation or other secondary gain may have functional visual loss. It is often difficult to separate real disability from nonorganic visual abnormalities in patients who are malingering.

Hallucinations and other visual disturbances observed in patients with head trauma also may be caused by medications, migraine, encephalitis, hepatitis, or other systemic disorders. Other causes of convergence insufficiency are wide interpupillary distance, refractive errors, delayed development, malnutrition, encephalitis, hepatitis, and drug intoxication.

## Systemic Associations

TBI is sudden and devastating. The patient may be in deep coma or have multiple injuries that affect motor function, speech, and cognition. With a mild TBI, visual symptoms can be part of the postconcussion syndrome. Sometimes, the head injury may seem quite minor, with no loss of consciousness. Early symptoms of TBI include headache, dizziness, vertigo, tinnitus, hearing loss, blurred vision, diplopia, convergence insufficiency, sensitivity to light and noise, diminished sense of taste and smell, irritability, fatigue, sleep disturbances, decreased libido, decreased appetite, short- and intermediate-term memory dysfunction, impaired concentration and attention, and slowing of reaction time.<sup>7</sup> Anxiety, depression, and personality changes may occur later and are confounded by social and economic comorbidity.<sup>8</sup>

## Pathology

A structural injury, such as a skull fracture, hematoma, contusion, stroke, or foreign body, accounts for many of the neurological sequelae of severe head trauma. The rigid skull encasement means that secondary pressure effects from intracranial injuries are common. The cranial nerves are susceptible to injury because of their long course at the base of the skull. Orbital fractures can lead to muscle entrapment and diplopia. Optic canal fractures, often associated with basilar skull fractures, can produce an optic neuropathy.

The pathophysiology of mild TBI is not understood completely. Subtle changes may be missed on neuroimaging studies. The most apparent neuropathological change in mild traumatic brain injury is diffuse axonal damage.<sup>9</sup> Acutely, the axons are damaged and swollen. This may be attributed to stretching of axons during the injury, with subsequent edema and detachment. The secondary changes of edema and disconnection may take 4–24 hours to develop. The synaptic terminals derived from the degenerating axons are disrupted, which results in diffuse deafferentation. Animal models of TBI suggest that an active neuroplastic response occurs, with repopulation of injured axon terminals by the remaining intact fiber populations. Changes in neurotransmitters are likely to occur in TBI. Excitatory neurotoxins are released acutely. Acetylcholine is increased in the cerebrospinal fluid and in several areas of the brain after injury. Altered binding to cholinergic and glutaminergic receptors occurs in the cerebral cortex.

## Treatment

Early diagnosis of visual problems after TBI is essential to maximize the overall rehabilitation potential.<sup>1</sup> The sooner the visual problems are addressed after head trauma, the better the chances for a faster and more

complete recovery. Treatments advocated for posttraumatic visual symptoms include eye exercises, prism spectacles, and surgery. Treatment should emphasize the design of lenses, filters, or prisms to address the specific defect in the visual system. Accommodative insufficiency is typically corrected by using a plus power that is often excessive for the patient's age. Patients who have hemianopic field defects require visual retraining to move the eyes and head consciously into the blind hemifield. In addition, computer-based training programs have been developed to improve visual function in patients with visual field defects.<sup>10</sup> Occasionally, prisms are useful in these patients to shift part of the missing hemifield into view. Other techniques for reading include using guides for lines and margins and moving or tilting the page into the intact visual field. Therapists and caregivers must be aware of the patient's visual limitations that militate against adaptation to activities of daily life. Single vision reading spectacles may help patients who have inferior visual field defects.

Patients who have diplopia are helped by prisms, patching, or surgery. Prisms are most useful for relatively comitant ocular deviations. Because most patients improve, a temporary Fresnel prism allows easy prism replacement as the strabismus lessens over time. Patching one eye may reduce discomfort initially, but in the long term, this produces a monocular condition that stresses the visual and motor systems, causing difficulty with midline concepts and affecting balance and posture. Strabismus surgery should not be considered for at least 9 months after the injury because a high rate of spontaneous improvement occurs. Visual rehabilitation may include activities designed to enhance the patient's awareness of visual deficits and increase function to maximize residual vision.

## Course and Outcome

The visual system impacts all aspects of life. Rehabilitation is much more difficult if the visual system is not efficient. Patients who have severe brain injuries often have permanent visual field and motility defects. The Glasgow Coma Scale, a measure of the depth of coma, is useful for predicting overall functional outcome when applied on the second or third day after injury. Posttraumatic amnesia that persists for more than 2 months is a poor prognostic sign with regard to independent living, memory, and work capacity.

Most patients who have mild TBI experience improvement. The majority recovers completely within the first year after sustaining the injury. These patients should be reassured that their symptoms are valid and their prognosis is good. Headaches, dizziness, and memory problems are the primary symptoms associated with mild head injury; most patients have resolution of these symptoms by 6 months. It is not uncommon for patients to complain of diplopia many months after suffering the injury, although most cases of diplopia tend to resolve spontaneously in 6–12 months. Those with a late onset of symptoms may have an underlying psychogenic cause. Patients who have convergence insufficiency secondary to trauma and those who have idiopathic convergence insufficiency do not seem to respond to treatment.

## DRUGS, TOXINS, AND THE BRAIN

### Introduction

Visual phenomena are observed with an endless list of drugs, including prescription medications. Many neurotoxic agents have a major effect on the visual pathways.

### Epidemiology and Pathogenesis

Hallucinations and other visual symptoms are induced by hallucinogens and stimulants, but they are also reported frequently as side effects of a variety of medications commonly used in clinical practice. Visual disturbances from digitalis were observed more than 200 years ago and are experienced by up to 95% of patients, particularly those who have digitalis intoxication.<sup>11</sup> As early as 1843, cases of cerebral blindness secondary to carbon monoxide poisoning were reported.<sup>12</sup> Toxic levels of many chemical substances, such as toluene and other solvents, can produce devastating visual deficits. The deliberate inhalation of volatile substances to achieve intoxication has been associated with pleasant as well as unpleasant visual changes. Abuse of volatile substances is seen in most parts of the world, mainly among adolescents, individuals living in remote communities, and those whose occupations afford ready access to such substances.<sup>13</sup>

## Ocular Manifestations

Hallucination is a potential side effect of many medications. The most common medications with hallucinogenic potential are histamine 2 (H<sub>2</sub>) blockers, dopaminergic agents, antihypertensives, anticholinergics, sedative hypnotics, benzodiazepines, antidepressants, anti-inflammatory agents, and corticosteroids.<sup>14</sup> Many of the mydriatic and parasympatholytic drugs (e.g., scopolamine [hyoscine], atropine, cyclopentolate) used in ophthalmology have considerable hallucinogenic potential. Amantadine, atropine, and other anticholinergics may produce “Lilliputian” hallucinations, in which people appear greatly reduced in size.<sup>15</sup> Visual symptoms from digitalis include dimness; scotomata; flickering or flashing lights of yellow, green, or red; haloes; cycloplegia; amblyopia; diplopia; and blindness. Hydroxychloroquine has similar side effects, as well as photophobia and oculogyric crisis. Perception of a bluish haze and increased light sensitivity may occur with sildenafil use.<sup>16</sup> Hallucinogenic phenomena, particularly visual hallucinations, are observed with lysergic acid diethylamide, amphetamines, cocaine, marijuana, phencyclidine, and inhalants. Lysergic acid and several prescribed medications, such as trazodone, mirtazapine and topiramate have been linked to akinetopsia (abnormal movement perception) and palinopsia (perseveration of a visual image in time). The visual experiences of lead encephalopathy may resemble delirium tremens, with illusions or misperceptions of objects and shadows.

Many types of visual complaints follow carbon monoxide toxicity. Visual field defects range from concentric constriction to homonymous hemianopia. Patients often have fluctuating visual acuity with normal pupils, typical of an occipital lobe process. Visual object agnosia, polyopia, metamorphopsia, kakopsia (abnormally bright appearance of colors), and asthenopia (cerebral blurred vision) may occur. A distinct clinical syndrome grouped under the term *mitochondrial optic neuropathy* (MON) can be caused by several drugs, including ethambutol, chloramphenicol, linezolid, erythromycin, streptomycin, and antiretroviral agents.<sup>17</sup> MON is characterized by slowly progressive bilateral loss of central vision, dyschromatopsia, central or cecentral scotomas, and loss of high spatial frequency contrast sensitivity.

## Diagnosis and Ancillary Testing

For the evaluation of a patient who has unexplained visual loss or visual disturbances, a detailed history is required; this includes determining the usage of prescription and nonprescription drugs, the ingestion of herbal and other natural remedies, and possible environmental exposure to toxins or chemicals. In suspected cases of toxic exposure, toxicological analysis of blood, urine, and tissue is indicated. Optical coherence tomography is a useful ancillary test in drug-related retinopathy or optic neuropathy. MRI may reveal abnormalities in the basal ganglia or the occipital lobes with carbon monoxide poisoning (Figs. 9.25.1 and 9.25.2).

## Differential Diagnosis

Intracranial lesions, visual loss, vitreous or retinal detachment, seizures, migraine, and metabolic abnormalities must be considered in the evaluation of hallucinations. Both formed and unformed hallucinations occasionally occur with intracranial tumors, infarcts, and vascular malformations. Lesions in the temporal lobe typically produce formed images, whereas unformed, geometrical patterns arise from the occipital lobe. Vivid hallucinations may accompany a thalamic or midbrain infarction.<sup>18</sup> Patients who have a homonymous hemianopia may see images in their blind hemifield.<sup>19</sup> Partial seizures sometimes are accompanied by visual disturbances, which may herald the impending seizure. Positive and negative visual phenomena are common features of migraine with or without headache.

Metabolic derangements usually produce hallucinations with an encephalopathy. Flashes and floaters of ocular origin typically are monocular. Charles Bonnet's syndrome consists of formed hallucinations in patients who have bilateral visual loss. Typically, these are nonthreatening, and the patient knows that the apparitions are not real.<sup>20</sup> Formed and unformed hallucinations are also common in patients with retinal disease and often are not reported.<sup>21</sup> Patients who have bilateral blindness may see formed or unformed hallucinations as a release phenomenon. The visual hallucinations of psychiatric disease most often can be menacing and are accompanied by auditory hallucinations.

**Fig. 9.25.1** Magnetic resonance imaging of the brain shows areas of infarction following carbon monoxide poisoning. This T2-weighted image shows abnormally high signal intensity in the basal ganglia, right frontal lobe, and cerebral cortex.

**Fig. 9.25.2** Bilateral cavitory lesions in the globus pallidus following carbon monoxide poisoning.

## Systemic Associations

Headache, fatigue, malaise, and drowsiness are side effects of many drugs. Hallucinogens are absorbed efficiently from the gastrointestinal tract, and this results in multiple systemic effects, such as disordered thought processes, mood changes, anorexia, tachypnea, tremors, hyperreflexia, hypertension, and tachycardia. Hallucinogens, medication reactions, and toxins can produce hallucinations that resemble psychiatric states.<sup>14</sup>

## Pathology

Some drugs affect the visual system by their effects on the ocular media, retina, and optic nerve. The anticonvulsant vigabatrin produces irreversible visual field loss by its effect on inner electroretinal function at the level of the Müller cell. Vigabatrin also produces outer retinal dysfunction that may be reversible.<sup>22,23</sup> Macular edema is a dose-dependent adverse effect of fingolimod, the first approved oral agent for the treatment of relapsing forms of multiple sclerosis, with an incidence of 0.4% at the recommended dose of 0.5 mg/day.<sup>24</sup> Drugs that cause MON are thought to block mitochondrial oxidative phosphorylation processes affecting the more vulnerable fibers of the papillomacular bundle (Fig. 9.25.3).<sup>17</sup> Treatment with tumor necrosis factor- $\alpha$  blockers may predispose patients to develop central nervous system demyelinating disease, including optic neuritis.<sup>25</sup> Nonarteritic anterior ischemic optic neuropathy has been reported in temporal association with the use of phosphodiesterase type 5 inhibitors used for treating erectile dysfunction.<sup>26</sup> In other cases, drugs have direct action on the brain cells. The dopaminergic and cholinergic neurons in mesolimbic pathways may be important in the development of hallucinations. Digitalis and other toxic agents produce visual changes as a result of profound excitatory effects on nerve cells. Severe reduction in visual acuity in patients who have carbon monoxide poisoning is thought to result from cerebral blindness secondary to brain anoxia.

**Fig. 9.25.3** Accumulation of reactive oxygen species (ROS) leads to a decrease in the electrical potential across the mitochondrial membrane, which allows for an opening of the mitochondrial permeability transition pore (MPTP), allowing for leakage of cytochrome c (Cyt c) into the cytosol. Cyt c then binds to apoptosis activating factor-1 (APAF-1), which activates procaspase-9, triggering the caspase cascade and apoptosis. (Source: Drug-related mitochondrial optic neuropathies. *J Neuroophthalmol* 2013 Jun;33(2):172–8.)

## Treatment, Course, and Outcome

The most important aspect of treatment is removal of the source of exposure. Hallucinations induced by hallucinogenic drugs can also be treated effectively with antipsychotic medications. Treatment of carbon monoxide poisoning consists of inhalation of supplemental oxygen and aggressive supportive care, including hyperbaric oxygen therapy for selected cases.<sup>27</sup>

# Vascular Disorders

Peter A. Quiros, Michelle Y. Wang

# 9.26

**Definition:** Vascular lesions are congenital or acquired abnormalities of blood vessels and may affect any part of the sensory and motor visual pathways.

## Key Feature

- Aneurysms, carotid-cavernous fistulas and shunts, and arteriovenous malformations can produce damage to the eye and brain and have discrete, often disparate, clinical features and management.

## Associated Features

- Transient visual loss, both monocular and binocular, may or may not be associated with demonstrable vascular lesions.
- Transient ischemic attacks and stroke manifest characteristic symptoms and signs. Their diagnosis, investigation, and management depend on the locale of the insult to the central nervous system.

## INTRODUCTION

The visual pathways and oculomotor system can be affected by virtually all types of vascular diseases. Aneurysms most commonly cause third nerve palsy, although visual loss also may occur. Carotid-cavernous (C-C) fistulas, especially shunts, can be mistaken for other more benign causes of an inflamed eye. Arteriovenous malformations (AVMs), especially cryptic AVMs, can cause highly variable cerebral neurological deficits. Transient visual loss (TVL) and cerebral ischemic attacks cause concern about impending stroke.

## ANEURYSMS

### Epidemiology and Pathogenesis

The incidence of saccular aneurysms is estimated at 1%–2%.<sup>1</sup> Most saccular aneurysms occur as isolated, nonhereditary lesions. However, because intracranial aneurysms of 2 mm or smaller are found in 70% of routine autopsies, this incidence is significantly underestimated. Women are more susceptible, especially to internal carotid-posterior communicating (PCOM) artery aneurysms. The peak incidence of aneurysms occurs during the fifth and sixth decades. About 85% of aneurysms originate from branches of the internal carotid artery (ICA), usually at the PCOM or ophthalmic artery or within the cavernous sinus. The rupture rate depends on the size and location of the aneurysms, with the ones in the posterior circulation and PCOM artery being the highest risk locations. The International Study of Unruptured Intracranial Aneurysms conducted a retrospective study on 727 patients without a history of subarachnoid hemorrhage from a different aneurysm and 722 patients with a history of ruptured aneurysm. The rupture rate was 0.5% per year for aneurysms less than 10 mm in patients with a history of prior rupture and the risk increased to 0.7% per year for aneurysms 10 mm or larger. Those without a history of prior rupture had a lower risk.<sup>2</sup> Aneurysms may be multiple in about 25% of adults.<sup>2</sup>

### Ocular Manifestations

Aneurysms that affect the following portions of the circle of Willis have ophthalmological manifestations:

- The PCOM-ICA junction—causing third nerve palsy.
- The carotid-ophthalmic artery junction—causing compression of the optic nerve, optic chiasm, or both.
- The intracavernous carotid artery—causing dysfunction of isolated or multiple cranial nerves, including the oculomotor, trochlear, abducens, trigeminal nerves, and (rarely) optic nerves.

PCOM artery aneurysms most commonly affect young women; they can manifest as a sudden apoplectic event as a result of subarachnoid hemorrhage or produce third nerve palsy by slow enlargement without rupture.<sup>3</sup> This type of aneurysm is responsible for 13%–30% of acquired oculomotor palsy<sup>4,5</sup>; 90% of otherwise asymptomatic, unruptured PCOM artery aneurysms cause signs of third nerve palsy.

Carotid-ophthalmic aneurysms (rarer than PCOM artery aneurysms) affect the sensory visual pathways by compression of the optic nerve and chiasm, occur most commonly in women during the fourth to seventh decades of life, and often are associated with other intracranial aneurysms. Carotid-ophthalmic aneurysms may rupture and cause subarachnoid hemorrhage, but most often they produce symptoms by compression of the adjacent optic nerves and chiasm,<sup>6</sup> and this results in unilateral visual loss with an inferior visual field defect. These aneurysms arise from the ophthalmic artery beneath the optic nerve and compress the nerve superiorly against the superior dural shelf of the optic canal.<sup>7</sup> Insidious, slowly progressive visual loss occurs in most cases. Rarely, an acute painful course with central scotoma and ipsilateral afferent pupillary deficit can mimic retrobulbar optic neuritis.<sup>8</sup> When ophthalmic aneurysms expand posteriorly and superiorly, chiasmal or optic tract syndromes can be seen. Medial expansion may even compress the contralateral optic nerve.<sup>9</sup>

The main difference between PCOM artery aneurysms and internal carotid-ophthalmic aneurysms is that the former produce motor (third cranial nerve) signs and symptoms and the latter produce sensory (optic nerve and chiasm) symptoms and signs.

Aneurysms that arise from the internal carotid artery within the cavernous sinus behave differently. They can grow to quite a large size before rupturing; when they do rupture into the cavernous sinus, they may produce a C-C sinus fistula.

Intracavernous carotid aneurysms enlarge gradually within the cavernous sinus. Anterior expansion may erode the optic foramen and the superior orbital fissure, resulting in compressive optic neuropathy, ocular motor nerve paresis, and proptosis.<sup>3</sup> Erosion medially into the sella may produce hypopituitarism.

Patients with unruptured intracavernous aneurysms have cranial nerve palsies, with the sixth cranial nerve involved most commonly. The trigeminal nerve may be involved late in the disease, which results in facial pain.<sup>10</sup> Apparent pupillary sparing of the third cranial nerve may occur because of involvement of both oculosympathetic and parasympathetic pupillary pathways.<sup>11</sup>

Most patients who develop an acute oculomotor nerve paresis are left with a permanent disorder—often with secondary oculomotor nerve synkinesis or develop aberrant regeneration (including lid retraction on downgaze; Fig. 9.26.1) despite no previous acute third nerve dysfunction. Primary oculomotor nerve synkinesis more commonly occurs with meningiomas.<sup>12</sup>

Trigeminal nerve dysfunction commonly accompanies intracavernous aneurysms.<sup>13</sup> The first division of the fifth cranial nerve is affected most often. Pain usually is constant, lancinating, and severe, but it can be episodic. Trigeminal sensory loss is rare, and only occurs late in the disease.

Visual loss is not as characteristic of intracavernous aneurysm as it is with ophthalmic aneurysms, unless the aneurysm arises from the most distal portion of the intracavernous artery.

**Fig. 9.26.1** A 36-Year-Old Patient With Aberrant Regeneration—Third Cranial Nerve Synkinesis. (A) Ptosis. (B) Medial rectus paresis with lid retraction on adduction. (C) Typical lid retraction on downgaze. (D) Magnetic resonance angiogram showing internal carotid-posterior communicating artery aneurysm (arrow).

## Diagnosis

Three clinical signs usually are apparent:

- Ipsilateral facial, orbital, or eye pain.
- Extraocular muscle and levator involvement.
- Pupillary paresis.

### Head Pain

Head pain can be caused by both ruptured and unruptured aneurysms. Ruptured aneurysm pain is severe, sudden in onset, throbbing, and radiates posteriorly. Neck pain and stiffness are signs of subarachnoid hemorrhage. Third nerve palsy most commonly occurs concomitantly but may not develop for hours or days. Headache and eye pain from unruptured aneurysms may occur intermittently for weeks or months before third nerve palsy or aneurysm rupture occurs.

### Ophthalmoplegia

Ophthalmoplegia is variable but develops in virtually all patients eventually. Ptosis and extraocular motor paresis occur at the same time almost invariably, especially with ruptured aneurysms. An apoplectic onset with subarachnoid hemorrhage may overshadow the signs of diplopia or ptosis. Any muscle supplied by the third cranial nerve can be affected; however, the superior rectus and levator muscles are damaged most commonly because the aneurysm presses on the nerve from above in the subarachnoid space (Fig. 9.26.2).

### Pupillary Involvement

Pupillary involvement can be the initial sign of an unruptured or “about to rupture” aneurysm but is rarely, if ever, an isolated sign in a ruptured aneurysm. Pupillary dilatation may occur shortly before, at the same time, or shortly after oculomotor paresis occurs. Pupil involvement mandates immediate efforts to rule out an aneurysm by magnetic resonance imaging (MRI) or magnetic resonance angiography (MRA). Computed tomography angiography (CTA) is also very useful in detecting these aneurysms,<sup>14</sup> but digital subtraction angiography is still the gold standard. In an emergency, computed tomography (CT) can be performed immediately to rule out subarachnoid hemorrhage. Complete pupil sparing, which may accompany extraocular muscle paresis with a PCOM artery aneurysm, has been reported rarely.<sup>15,16</sup> Although pupil involvement can be seen in as many as 20% of patients with ischemic oculomotor palsies, anisocoria of more than 1.5 mm is very rare.<sup>17</sup>

## Differential Diagnosis

The appropriate ophthalmic management of possible aneurysms is to make the right diagnosis expeditiously. Any patient with a possible third nerve palsy should be observed carefully for pupillary dysfunction. Complete third cranial nerve paresis and a normal pupil are extremely unlikely in a patient with an aneurysm.<sup>18</sup>

However, Miller<sup>3</sup> states that any patient with an incomplete oculomotor palsy and a normal pupil should undergo neuroimaging. When aneurysms are greater than 4 mm in diameter, they can be demonstrated by dynamic CT and MRI,<sup>19</sup> as well as MRA. The author feels, however, that an older patient with hypertension or diabetes, without head pain, need be only observed because most likely there is a microvascular etiology for the third nerve palsy. Symptoms and signs may occur directly after injury or several days to weeks later. Although relatively rare, direct fistulas may develop spontaneously. Such patients may suffer from diffuse arterial disease manifested by aortic, femoral, and popliteal aneurysms,<sup>20</sup> as well as other signs of large vessel disease, such as systemic hypertension, arteriosclerosis,<sup>21</sup> or an underlying connective tissue disorder.

## Treatment, Course, and Outcome

Recovery of extraocular muscle function occurs in most patients with PCOM artery aneurysms, either spontaneously or after surgical treatment, whether or not the aneurysm has ruptured. Recovery is most likely in incomplete paresis, when no rupture has occurred and when successful clipping is performed within 1–2 weeks of onset.<sup>22</sup> Incomplete recovery after several months leaves secondary oculomotor nerve synkinesis or aberrant regeneration of the oculomotor nerve (see Fig. 9.26.1).

## CAROTID-CAVERNOUS SINUS FISTULAS AND DURAL SHUNTS

### Epidemiology and Pathogenesis

Abnormal communications between the cavernous sinus and dural veins and the carotid arterial system can be classified according to cause (traumatic versus spontaneous), velocity of blood flow (high versus low flow), and anatomy (direct [sinus] versus indirect [dural]; internal carotid versus external carotid, versus both). C-C fistulas, characterized by direct flow into the cavernous sinus from the intracavernous carotid artery, are of the high-flow type; these usually are traumatic and most often diagnosed in young men. Nontraumatic, low-flow dural fistulas may develop spontaneously or with atherosclerosis, hypertension, collagen vascular disease, and during or after childbirth; these fistulas more often are seen in middle-aged women. Spontaneous shunts occur between the cavernous sinus and one or more meningeal branches of the internal carotid artery (usually the meningohypophyseal trunk), the external carotid artery, or both. These shunts have a low amount of arterial flow and almost always produce signs and symptoms spontaneously.

Dural shunts between the arterial and venous systems have lower flow, yet they may produce symptoms in younger patients spontaneously or in older patients as a result of hypertension, diabetes, atherosclerosis, or other vascular disorders. Anatomically, these shunts arise between the meningeal arterial branches and the dural veins. The meningohypophyseal

**Fig. 9.26.2** A 40-Year-Old Patient With Right Internal Carotid-Posterior Communicating Artery Aneurysm. (A) Primary position ptosis. (B) Paralysis of vertical gaze and dilated pupil. (C-D) Arteriograms showing internal carotid-posterior communicating artery aneurysm directed down, out, and inferiorly on the third cranial nerve (arrows).

trunk and the artery of the inferior cavernous sinus provide the arterial supply to most dural shunts.<sup>23</sup>

Such shunts may be caused by an expansion of congenital arteriovenous malformation<sup>24</sup> or spontaneous rupture of one of the thin-walled dural arteries that traverse the sinus.<sup>25</sup>

## Ocular Manifestations

Ocular signs of C-C fistulas are related to venous congestion and reduced arterial blood flow to the orbit. Diminished arterial flow to cranial nerves within the cavernous sinus may cause diplopia. Stasis of venous and arterial circulation within the eye and orbit may cause ocular ischemia, and increased episcleral venous pressure may cause glaucoma. These abnormalities usually are unilateral, but they can be bilateral or even contralateral to the fistula.<sup>26,27</sup>

Exophthalmos is a common sign that occurs in almost all patients who have C-C fistulas; rapid-flow fistulas may cause exophthalmos within hours or several days. The orbit can become “frozen,” with no ocular motor function. Usually, this is accompanied by conjunctival chemosis and hemorrhage. Vision may be reduced markedly because of optic nerve ischemia.<sup>28</sup>

“Pulsating exophthalmos” is uncommon in C-C fistula. Usually, the orbit is too rigid from hemorrhage and edema for “pulsation.”

Chemosis of the conjunctiva and arterialization of the episcleral vessels occurs in most patients. Arterialization of episcleral veins is the hallmark of all C-C fistulas or dural shunts (Fig. 9.26.3).

Bruits associated with fistulas and dural shunts can be appreciated both subjectively and objectively. A bruit can be heard best when the examiner uses a bell stethoscope over the closed eye, over the superior orbital vein, or over the temple. A bruit is not pathognomonic of C-C fistula. It also can be heard in normal infants, in young children, and in patients with severe anemia.

In cases of C-C fistula, the abducens nerve is affected most often because it lies in the cavernous sinus itself. Because the third and fourth

cranial nerves are encased in the superior internal dural wall of the sinus, they may be protected from changes caused by the fistula.<sup>29</sup> Mechanical restriction from venous congestion and orbital edema also may contribute to limitation of eye movements.

Immediate or delayed visual loss occurs frequently in direct C-C fistulas<sup>29</sup> because of optic nerve ischemia from apical orbital compression. Long-standing fistulas can lead to loss of vision from distension of the cavernous sinus or retrobulbar ischemia.<sup>28</sup>

Ophthalmoscopic findings caused by venous stasis and impaired retinal blood flow include retinal venous engorgement and dot-and-blot retinal hemorrhages. Central retinal vein occlusion may be observed in high-velocity C-C fistulas with arterialized venous channels. In the unusual cases of central vein occlusion, neovascular glaucoma can occur.

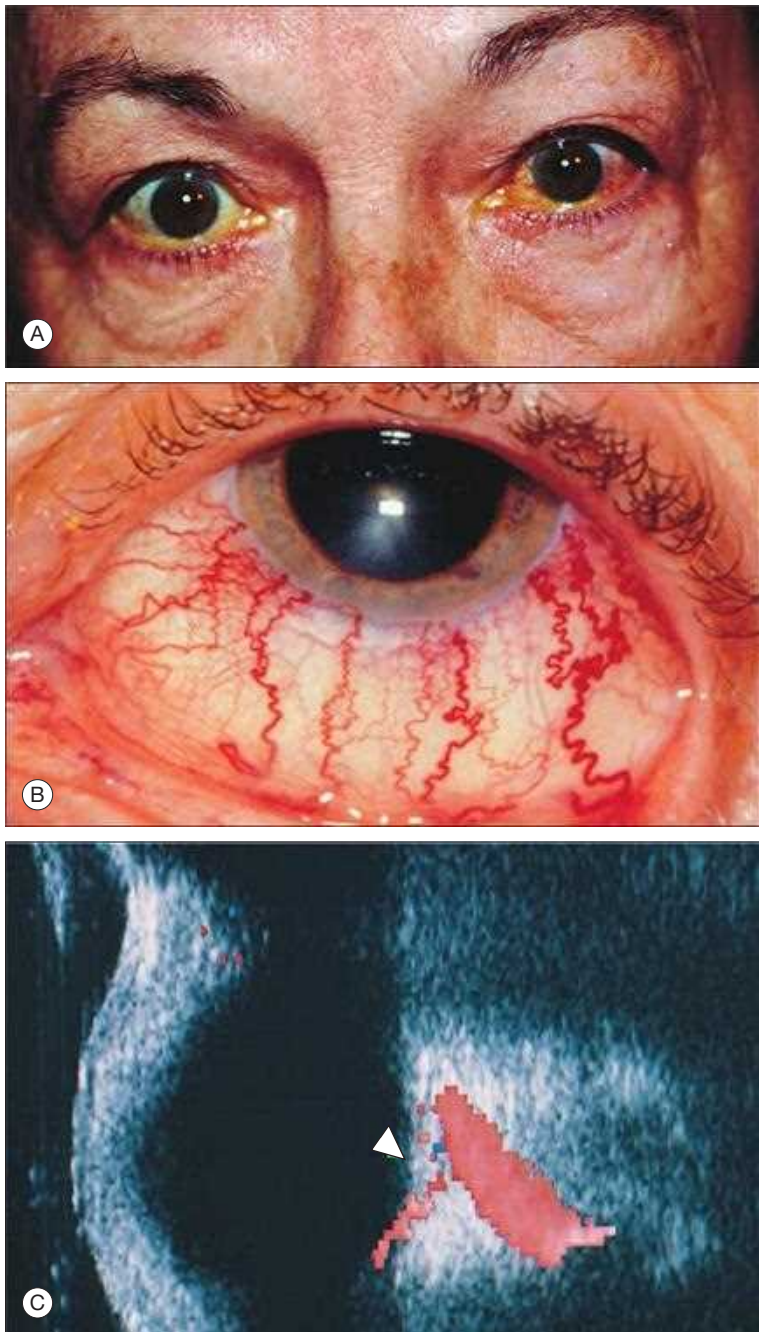

Misdiagnosis is more common with dural shunts than with C-C fistulas. Dural shunts may be mistaken for chronic conjunctivitis, orbital cellulitis, orbital pseudo-tumor, or thyroid disease.<sup>30</sup> However, in dural shunts the palpebral conjunctiva is not involved, and the bulbar vessels are not affected as diffusely as in inflammatory processes. Signs of dural shunt usually are unilateral, but they can be bilateral or even contralateral to the shunt.<sup>27</sup> Enlargement of the superior ophthalmic vein on contrast-enhanced CT or MRI is a telltale sign of most fistulas.

Exophthalmos generally occurs to a varying degree (see Fig. 9.26.3A and B), and ocular motor (usually abducens) palsies may be seen. A subjective bruit (heard by the patient) almost always can be obtained from the history; however, an objective bruit heard over the orbit or temple by auscultation is relatively uncommon.<sup>3</sup> Wide pulsation of Schiötz or applanation intraocular pressure amplitude is an important clue to the diagnosis.

## Differential Diagnosis

A direct C-C fistula should be suspected in any patient who suddenly develops a red eye with chemosis and exophthalmos, especially after head trauma. Orbital ultrasonography, CT, and MRI often show a “hockey stick”

**Fig. 9.26.3 Exophthalmos.** (A) A 60-year-old female patient, who has left chronic “red eye.” (B) Corkscrew (arterialized) vessels caused by low-flow (carotid–cavernous sinus) fistula. (C) Color Doppler image that shows impedance and reversal of flow in superior orbital vein (arrow). (B, Courtesy Dr. Christopher Kelley, Wills Eye Hospital.)

sign of an engorged superior ophthalmic vein, which also may be demonstrated by Doppler imaging. The ultimate test, however, is selective arteriography of both internal and external carotid arteries.

Treatment, Course, and Outcome

As with a C-C fistula, the diagnosis of a dural shunt can be made using CT, MRI, and Doppler imaging because each reveals superior ophthalmic vein enlargement (see Fig. 9.26.3C). Carotid color Doppler imaging may show reversal of flow in the ophthalmic artery, which may help to establish the diagnosis (see Fig. 9.26.3C).<sup>31</sup> CTA and MRA can also be helpful in the diagnosis of C-C fistula. However, selective intra-arterial angiography is usually necessary to define the dural shunt, and angiography remains the gold standard test.

Many patients with dural shunts improve spontaneously. Thus, proper diagnosis, reassurance, and conservative follow-up usually suffice.<sup>30,32</sup> However, embolization is necessary in patients with leptomeningeal venous drainage, variceal or aneurysmal venous dilation,<sup>33</sup> as well as those with visual loss (e.g., central vein occlusion), diplopia, severe exophthalmos, uncontrolled intraocular pressure, or intolerable bruit.<sup>34</sup> Although significant risks of neurological or visual sequelae from treatment must

TABLE 9.26.1 Terminology of Transient Visual Loss		
Type	Duration	Characteristics
Transient Monocular Visual Loss		
Visual obscuration	Seconds to minutes	Optic disc swelling and anomalies
Amaurosis fugax	Seconds to minutes	Often altitudinal; carotid, cardiac source (embolic) or vasospastic
Prolonged transient	15–60 minutes	Hypertension; hematopoietic visual loss and other systemic (vascular) problems; “retinal” migraine
Transient Binocular Visual Loss		
Aura without Headache	10–30 minutes	No other symptoms

be considered, treatment of the dural fistula should precede surgery in cases of high intraocular pressure. Endovascular treatment of the fistula via a transarterial or transvenous route often leads to resolution of visual deficits.<sup>32</sup>

The prognosis of direct C-C fistula varies, but severe visual loss is often immediate and permanent, especially when a “frozen orbit” is encountered. Some patients may not be aware of the visual loss because of an overriding concern for the chemosis, proptosis, and lid swelling.

Compared with the dural shunt syndrome, C-C fistula is a much more serious prognosis because direct fistulas do not resolve spontaneously and are less amenable to occlusive techniques. Expedient consultation with neurosurgery or neurointerventional radiology for fistula closure is indicated. The optimal treatment of C-C fistula is closure of the fistula along with preservation of carotid artery patency. Older procedures that required occlusion of the carotid artery to trap the fistula resulted in orbital hypoxia, which often made matters worse.

Endovascular closure has become the choice of treatment for C-C fistula.<sup>35</sup> Complications, such as worsening of orbital congestion and ocular motor nerve paresis, may occur. Fortunately, these complications are usually transient.<sup>3</sup> Successful occlusion usually results in gradual resolution of orbital signs within days, weeks, or sometimes months. Visual loss is often permanent.<sup>26</sup>

Arteriovenous Malformations

AVMs are the most common form of intracranial vascular hamartoma. The occasional relationship between cerebral (mesencephalic) and retinal AVMs was recognized first by Wyburn-Mason in 1943.<sup>36</sup> Most intracranial AVMs involve only pial vessels, but some involve both pial and dural vessels. Most AVMs are of congenital origin, but those that involve the meningeal arteries or vertebral arteries that drain into the dural sinuses may be acquired.<sup>23</sup>

AVMs that are only a few millimeters in size cannot be identified by neuroimaging and are referred to as *cryptic* or *occult*. Conversely, AVMs may be so large as to occupy an entire cerebral hemisphere. Although AVMs usually are congenital, they may become symptomatic at any age. However, 70% of AVMs produce symptoms during the second and third decades of life.

Most cerebral AVMs produce signs of intracerebral or subarachnoid hemorrhage, which include seizures or isolated neurological symptoms and signs. Headache is a frequent symptom and may mimic migraine, although the headaches always are on the same side, in contrast to typical migraines.

Improvements in microguidewire and microcatheter technology have made it possible to treat previously unreachable and untreatable AVMs. Treatment options include microsurgery, radiosurgery, and endovascular approaches. The specific techniques vary according to the anatomy of the lesion.<sup>37</sup>

TRANSIENT VISUAL LOSS

Epidemiology and Pathogenesis

TVL is a common symptom that may be benign or a harbinger of serious disease. Because clinical findings often are absent in patients with TVL, taking a medical history is imperative.

Ocular Manifestations

The terminology of TVL (Table 9.26.1) is important because it designates not only the anatomical location of the problem but also its pathogenesis.

Specific types of transient, monocular visual loss include transient visual obscurations, which are very brief (1–5 seconds) episodes of visual loss typically seen in patients with papilledema due to increased intracranial pressure), amaurosis fugax (1–5 minutes), caused by embolic or hemodynamic retinal arterial insufficiency, and prolonged monocular TVL, (>10 minutes), which occurs in patients with hypertension, blood dyscrasias, and “retinal migraine.” Binocular TVL may be seen with migraine, in the absence of headache (aura without headache), and in other rare binocular or homonymous disturbances caused by occipital ischemia or seizures.

Physical clues that help in the diagnosis of patients with TVL include abnormalities of vision, pupillary abnormalities, color vision loss, Amsler Chart defects, and abnormalities of the optic nerve or retina. The most important ocular finding in monocular TVL is an impacted embolus in the arteries within the optic nerve or in the retina. The appearance of different types of emboli can provide clues to the source. Localized, hard, white material suggests calcium, which may come from a damaged aortic or mitral valve. Platelet-fibrin emboli usually conform to a segment of a retinal branch arteriole and may have a white or gray appearance. Hollenhorst or cholesterol plaques are yellow or golden and tend to gleam (Fig. 9.26.4). Both platelet-fibrin emboli and cholesterol emboli can be missed easily, especially if they are small. Gentle pressure on the eye often makes the embolic material “light up,” which allows better visualization of an embolus (Fig. 9.26.5).<sup>38</sup>

Retinal emboli are the major cause of amaurosis fugax; the carotid artery is the likely source, although such emboli also can come from the

**Fig. 9.26.4** Cholesterol emboli impacted in superior and inferior retinal arterioles with branch occlusion (arrows).

**Fig. 9.26.5** Combined thromboplatelet retinal emboli digital pressure maneuver (arrows). (A) Before pressure. (B–D) During digital pressure on the eye to elicit previously only suspected embolus.

aorta or heart. Auscultation of a bruit in the neck at the angle of the jaw further indicates the need for carotid magnetic resonance arteriography or, at least, carotid Doppler imaging.

An often-neglected anterior sign in any of the ocular ischemic syndromes is sludging of the conjunctival microcirculation. Slit-lamp magnification with red-free light shows micropools and a varying degree of sludging in the conjunctival blood vessels when a vascular impedance or hyperviscosity is present. In patients with ocular ischemia from severe carotid artery stenosis or occlusion, TVL may occur when the eye on the affected side is exposed to bright light.

## Diagnosis

The age of the patient with TVL is very important—older patients with vasculopathy have different causes compared with younger individuals. The character of the episode must be ascertained in detail.

### Nature of the Episodes

The following need to be established:

- Where, when, and how did the episode occur?
- Did it appear and disappear suddenly or gradually?
- Did field loss occur, and, if it did, what type was it?

The typical curtain effect of altitudinal, monocular visual field loss is most significant because this implies carotid occlusive disease or a cardiac source.

### Type of Visual Loss

Monocularity is not always easy to determine. Although most patients with monocular TVL often are clear about monocularity, patients with binocular TVL or migraine aura commonly state that the right or left eye is involved when, in reality, loss of vision may have occurred only in the larger temporal homonymous visual field.

### Length of Episodes

The duration of transient monocular loss of vision caused by carotid artery disease typically lasts 1–5 minutes. The patient often does not initially calculate the duration accurately, but with recurrent attacks, both monocularity and duration are better appreciated.

### Frequency of Episodes

An isolated monocular attack may be sufficient to warrant investigation, at least with carotid Doppler studies. Recurrent attacks over a short interval are a strong indication for a full workup.

### Associated Symptoms

Accompanying symptoms usually are absent in TVL. It is the isolation that makes TVL episodes unique. It is rare for a patient with an isolated aura without headache to proffer any other neurological symptoms. Contralateral numbness or weakness that occurs with transient monocular loss of vision implies severe carotid stenosis. Cerebral TIAs imply either emboli to the brain or a hemodynamic cause, such as hypertension. Transient binocular blindness caused by posterior circulation ischemia from atherosclerosis often occurs with other symptoms of vertebrobasilar insufficiency, such as dizziness, lightheadedness, or syncope.

### Underlying Risk Factors

Contributory causes can be determined from a thorough history and appropriate investigation. Hypertension, diabetes, or hematopoietic disorders in all age groups are important. In young people, contraceptive pill use and congenital acquired heart disease must be excluded. In older patients, any history of myocardial, femoral, or aortic disease is an important indication of a diffuse arteriopathic state.

Young patients with TVL should be screened carefully for hyperviscosity or hypercoagulable disorders. Elevated antiphospholipid–cardiolipin antibody levels in a young woman with a strong history of migraine may be important. Cardiac workup may identify mitral and aortic valvular disease, mural thrombi, arrhythmia, especially intermittent atrial fibrillation, and patent foramen ovale.

## Treatment, Course, and Outcome

The goal in the management of patients with TVL is to prevent further episodes that could lead to permanent visual loss or cerebral stroke. However,

a single attack of monocular TVL does not necessitate invasive studies. Noninvasive carotid and orbital color Doppler imaging, when properly performed, may be sensitive enough to provide the required information; many patients who have TVL therefore may not require more invasive studies. Older patients with risk factors for large-vessel disease probably should be assessed by using MRA. Any patient with a history of cardiac signs or symptoms should be assessed by using echocardiography.

In summary, symptomatic patients with or without retinal emboli or a bruit should be assessed by using carotid and orbital color Doppler imaging or MRA. Invasive angiography may not be necessary.

## TRANSIENT ISOLATED BILATERAL LOSS OF VISION

### Aura Without Headache

Transient binocular loss of vision is one of the most common complaints encountered in ophthalmic practice. It has been called *acephalgic migraine*, *migraine accompaniment*, *visual migraine*, and *ophthalmic migraine*. The term *isolated aura without headache*, however, clearly identifies an isolated transient binocular attack, similar to that described as the aura or prodrome of migraine.

Symptoms may last from 15 seconds to 1 hour; however, the classic description of kaleidoscopic, heat-wave, or scintillating bright lights that last for 10–20 minutes confirms the diagnosis, which usually is a great relief to the patient.

Visual field testing sometimes should be performed. It is still the best way to be sure that stroke, AVM, or tumor is not the problem.

Monocular loss almost always needs investigation. Management of binocular episodes usually is conservative. The typical 10- to 20-minute attack of transient bilateral homonymous loss of vision with a kaleidoscopic or heat-wave visual disturbance is so characteristic of isolated aura without headache that a diagnosis can be made with confidence, the patient reassured, and no further investigation made. These patients primarily need reassurance and do not need further investigation unless extenuating circumstances are present.

## STROKES

### Epidemiology and Pathogenesis

#### Transient Ischemic Attacks and Stroke

The most reliable indicator of impending stroke is a transient ischemic attack (TIA). Vascular sites of disease that produce TIAs and stroke are as follows:

- Carotid–ophthalmic artery.
- Middle cerebral artery (MCA).
- Posterior cerebral (terminal basilar) artery.
- Basilar artery.

#### Carotid–Ophthalmic Ischemic Attacks and Stroke

Carotid–ophthalmic artery TIAs most commonly manifest as amaurosis fugax caused by hypoperfusion of the retina. The patient is at risk of permanent visual loss, usually from occlusion of the central retinal artery. This constitutes an ocular “stroke” and requires investigation of carotid, cardiac, and hemodynamic diseases (see Chapter 6.19).

Severe chronic common or bilateral internal carotid artery diseases may lead to hypoperfusion of the optic nerve and retina and cause the ocular ischemic syndrome (see Chapter 6.23). The hallmark of this syndrome is venous stasis retinopathy (Fig. 9.26.6).<sup>39,40</sup> Impacted cholesterol or platelet–fibrin emboli in the retina are an indication of carotid artery atheroma as the source; they are seen in 60%–70% of patients with branch retinal artery occlusion.<sup>41</sup> Nonarteritic ischemic optic neuropathy, both anterior and posterior, rarely may be the initial manifestation of internal carotid artery occlusion.

### Ocular Manifestations

Monocular blindness with contralateral hemispheric symptoms and signs (e.g., hemiparesis) is a well-recognized, although rare, entity in patients with carotid artery disease.<sup>42</sup> Blindness occurs as a result of retinal

**Fig. 9.26.6 Venous Stasis Retinopathy.** Typical diffuse dot-and-blot hemorrhages and venous dilatation without tortuosity in inferior fundus.

ischemia. However, these patients may have the simultaneous occurrence of cerebral infarction and ipsilateral ischemic optic neuropathy.<sup>43</sup>

Ocular ischemic syndrome causes insidious, slowly progressive loss of vision, in contrast to the acute loss resulting from retinal or optic nerve infarction. The affected eye is often injected, and vision is poorer than expected by the initial clinical examination. Neovascular glaucoma and vitreous hemorrhage often follow. Atherosclerotic occlusion or severe stenosis of the common, external, and internal carotid arteries is found in most patients who have a risk of stroke caused by poor cerebral perfusion<sup>44,45</sup> (see Chapter 6.23).

The second major ocular sign of carotid occlusive disease is partial or complete contralateral homonymous hemianopia,<sup>3</sup> often the result of hypoperfusion in the MCA, although posterior cerebral occlusion is, by far, the most common cause of homonymous hemianopia. Cerebral TIAs tend to be longer in duration compared with ocular TIAs. Ischemic reversible neurological deficit occurs when symptoms, such as numbness or weakness, disappear. When the defect persists, the term *stroke* should be used.

Ischemia of the cortical and deep cerebral branches of the left MCA produces isolated motor aphasia and, often, contralateral hemiparesis and sensory loss. When TIAs of the MCA are on the right (nondominant) side, transient motor or sensory loss is produced on the left, without aphasia.

The frequency of TIAs of the MCA is much less than that of internal carotid arteries (64% versus 20%); additionally, the internal carotid artery has more TIAs per patient (103 versus 3). Binocular TVL is not usually considered a manifestation of TIAs of the MCA, even though homonymous hemianopia is common in a completed MCA stroke. Caplan et al.<sup>46</sup> found TIAs of the MCA to be more common in people who are young, African American, and/or women.

The MCA stroke often fluctuates and progresses gradually. Anterior MCA branch occlusion produces hemiparesis in the leg and loss of sensation without hemianopia. Posterior MCA branch occlusion produces incomplete incongruous homonymous hemianopia, without macular sparing. Optokinetic responses may be reduced when stripes or checks are moved in the direction of the affected parietal lobe. Left MCA stroke produces aphasia, in contrast to right-sided lesions that produce contralateral hemispatial neglect and supranuclear horizontal gaze paresis toward the side of the lesion.

Homonymous hemianopia is the major neuro-ophthalmic sign of MCA stroke; it may be the only sign.<sup>3</sup> It is the result of damage to the optic radiations. The prognosis in MCA stroke is poor, but early treatment with intravenous tissue plasminogen activator may lead to greater recanalization rate and early neurological improvement.<sup>47</sup>

Transient visual symptoms caused by posterior cerebral artery (PCA) hypoperfusion are encountered less commonly and are less dramatic to the patient than amaurosis fugax of carotid origin. Isolated visual migraine must be differentiated from that of an impending stroke. Fisher<sup>41</sup> states that aura that occurs as a spectral march (buildup) or progression of the visual phenomenon often differentiates aura with or without headache from occipital TIA and stroke. Clinically, aura without headache is very common, in contrast to occipital TIA, although each can mimic the migraine with aura. True vascular TIAs that involve the occipital lobes

usually are sudden in onset, with a complete or incomplete homonymous hemianopia. They may be accompanied by vertebral-basilar symptoms, such as unsteadiness, dysarthria, facial numbness, or weakness.

Isolated homonymous hemianopias usually are caused by vascular occlusion of the PCA and thus are the hallmarks of occipital stroke. Infarction of the PCA is the result of embolism; rarely is it caused by atherosclerosis. Usually, PCA strokes occur without warning.<sup>48</sup>

Calcarine cortex infarction results in complete or incomplete hemianopia and usually spares the macular field. Invariably, hemianopia is congruous. A complete homonymous hemianopia spares the macula as a rule, and usually visual acuity is normal, although patients often complain of blurred vision. Many patients are unaware of the defect until it is pointed out.

Hemianopia with splitting of the macula often causes difficulty with reading. The Amsler chart or the Humphrey visual field is a valuable test by which to prove macular involvement; it also is a great asset when explaining the problem to the patient.

Clinically, homonymous hemianopia due to stroke in the temporo-parietal and occipital areas can be differentiated by diminished optokinetic nystagmus. When stripes or other stimuli are moved in the direction of a lesion that involves the deep parietal lobe, the responses are dampened, whereas in isolated occipital (calcarine) lesions the responses are equal. Improvement of the field defect is rare.

Hemianopia always should lead to inquiry as to other neurological deficits. Ophthalmologists should recognize alexia without agraphia, wherein the patient usually can name individual letters or numbers but cannot recognize simple words, although able to write words.<sup>49</sup> Right PCA occlusion can result in *prosopagnosia*, the inability to recognize familiar faces. Cerebral dyschromatopsia (color blindness) also can occur in occipital stroke. Rehabilitation is very difficult in permanent homonymous hemianopia.

Reduction in vertebral-basilar blood flow produces neurological and visual disturbances, from damage to the midbrain, pons, medulla, cerebellum, and occipital lobes. These disturbances may be transient, persistent, inconsequential, or catastrophic. Both extraocular movement and visual symptoms play a role in diagnosis.

In the vertebrobasilar territory, TIAs are much more varied than they are in the carotid system. Vertigo is the most common neurological symptom, along with dysarthria, transient weakness, drop attacks, and occipital headaches.<sup>3</sup> The most common visual symptom is a characteristic brief, binocular “white-out” of vision, which lasts a few seconds (rarely, up to 5 minutes). Transient diplopia is a rare symptom from ischemia of the ocular motor nerves or nuclei, or supranuclear and internuclear pathways. Typically, this symptom lasts 5–10 minutes. Episodic oscillopsia or “jumping vision” may occur during attacks of vertigo or dizziness.

The cause of vertebrobasilar TIA is speculative. Congenital vascular anomalies, hypertension, and hematological disorders are possible causes; however, atheromatous disease is the major problem in most patients.<sup>50</sup>

Stroke usually occurs without previous TIAs in vertebrobasilar disease. Hypertension and atherosclerosis are the most common causes, in addition to emboli from the heart or distal large arteries. Combined brainstem symptoms and signs include vestibular nystagmus, miotic pupils, and sixth cranial nerve, as well as conjugate gaze, internuclear, and facial palsies. Terminal PCA ischemia may occur alone or with a homonymous hemianopia. Lesions here can produce bilateral deficits, whereas carotid lesions produce unilateral deficits.

Brainstem signs most often arise from the lesions in the dorsal midbrain, primarily characterized by abnormal vertical gaze, upgaze, or downgaze paresis with lid retraction, or as isolated upgaze paresis. Pupillary signs, internuclear ophthalmoplegia, and skew deviation also may be present.

See-saw and convergence retraction nystagmus accompany periaqueductal midbrain infarction. The more ventral medial midbrain syndrome of oculomotor nerve dysfunction and contralateral hemiplegia (Weber’s syndrome) and Benedikt’s syndrome with contralateral cerebellar signs also may result from infarction of midbrain. Strokes that involve these structures can be identified by using MRI.

Pontine stroke produces primarily horizontal disorders of eye movement. Such strokes usually are associated with dizziness, facial nerve palsy, contralateral hemiparesis, hemisensory symptoms, and cerebellar signs. Isolated sixth nerve palsy without neurological signs also has been shown, by using MRI, to be caused by a fascicular lesion.<sup>51</sup> Unilateral internuclear ophthalmoplegia may be caused by infarction of the medial-longitudinal fasciculus in the pons.

# Electrophysiology

Rustum Karanjia, Stuart G. Coupland

# 9.27

**Definition:** Electrophysiology is an ancillary test that provides functional data on the inner and outer retina. In neuro-ophthalmology, it can be used to measure the electrical activity of the ganglion cells (pattern electroretinography and photopic negative response) and the occipital lobe (visual evoked potentials).

## Key Features

- Minimally invasive, reproducible, and quantitative.
- Defines and differentiates specific forms of optic neuropathy.
- Provides a direct functional measure of the ganglion cells.
- Helps correlate functional changes to anatomical changes in the retinal nerve fiber layer and macular ganglion cell layer.
- Useful adjuvant measures for following up patients with optic neuropathies.

## INTRODUCTION

Recording the electrical activity in the eye provides a useful objective measure of the function of the retina and the optic nerve. The utility of electrophysiology from a retina perspective is covered elsewhere (see Chapter 6.9). In neuro-ophthalmology, electrophysiology is used to assess patients suspected to have inorganic vision loss and those with possible optic nerve disease.

## NONORGANIC VISION LOSS

Nonorganic vision loss presents a diagnostic dilemma for most clinicians. Electrophysiology testing can be a useful adjunct to demonstrate that the visual system is functioning normally. This typically involves two types of assessments: (1) electroretinography (ERG) to assess retinal function and (2) visual evoked potentials (VEPs) to assess cortical function. Each of

these responses can be recorded in a variety of different ways. Full-field Ganzfeld stimulation can be used to record a full-field electroretinography (ff-ERG) or a flash or flicker VEP (f-VEP).<sup>1,2</sup> Pattern stimulation can be used to assess focal areas of the visual system by either pattern electroretinography (p-ERG)<sup>3</sup> or pattern VEP (p-VEP).<sup>2</sup> Furthermore, by altering the stimulus check size, an estimate of visual acuity can be obtained with a p-VEP (Fig. 9.27.1).<sup>4</sup> Assessment of retinal function is important when performing p-VEP because any deficiency in the retina will be reflected in an abnormal p-VEP. As the p-VEP correlates with central vision, a multifocal ERG (mf-ERG) is a recommended adjunct to ensure that there is no corresponding abnormality in the retina.

Choosing the appropriate test is dependent on the type of vision loss reported. Clinically, the objective in the assessment of nonorganic vision loss is to demonstrate that the patient's vision is better than the amount reported by the patient. The better the vision reported, the more clinically challenging it is. In patients who report no light perception, f-VEP can be useful to demonstrate that the system is functioning (Fig. 9.27.2). For patients with a reported vision of 20/80 or worse, a p-VEP can be useful to demonstrate better visual acuity.

Testing patients with nonorganic vision loss can also be technically challenging because patient cooperation can affect the quality of the data collected. Standards for clinical electrophysiology testing have been published by the International Society for Clinical Electrophysiology of Vision, and it rests with the treating physician to ensure that the testing is in compliance with these standards or to understand and explain any deviation from the standards.<sup>1-3</sup>

One essential element in testing patients with nonorganic vision loss is to ensure the patient is correctly fixating as all non-Ganzfeld stimuli require consistent accurate fixation. This can be monitored either directly by the test administrator or indirectly by using a pupil tracker. Lack of fixation can create some characteristic changes in the electrophysiological recordings, for example, a shift of the foveal peak on the mf-ERG (Fig. 9.27.3).

It is important to remember that the diagnosis of nonorganic vision loss is a diagnosis of exclusion. Thus, all appropriate tests must be performed

**Fig. 9.27.1 Normal Pattern Reversal Visual Evoked Potential (VEP) to Checkerboard Stimulation.** Check size is indicated in minutes of arc. A normal pattern VEP to 15-minute check size is consistent with visual acuity of 20/30 or better.<sup>4</sup> (From Gundogan FC, Sobaci G, Bayer A. Pattern visual evoked potentials in the assessment of visual acuity in malingering. *Ophthalmology* 2007;114(12):2332-7.)

**Fig. 9.27.2 Effect of True Light Perception Vision on the Flash and Flicker Visual Evoked Potential (VEP).** Set of flash and flicker VEPs from a patient with normal vision in the right eye and light perception vision in the left eye, demonstrating the effect of true light perception vision on the full-field VEP.

**Fig. 9.27.3 Effects of Fixation on Multifocal Electroretinography (mf-ERG).** The mf-ERG waveform morphology changes with eccentric fixation because of changes in stimulus hexagon scaling. The peak takes on an asymmetrical shape, with a sharp decline on one side and a shallower decline on the opposite side. This is characteristic with fixation deviation.

prior to arriving at this diagnosis, and electrophysiology is most useful to confirm the clinical diagnosis.

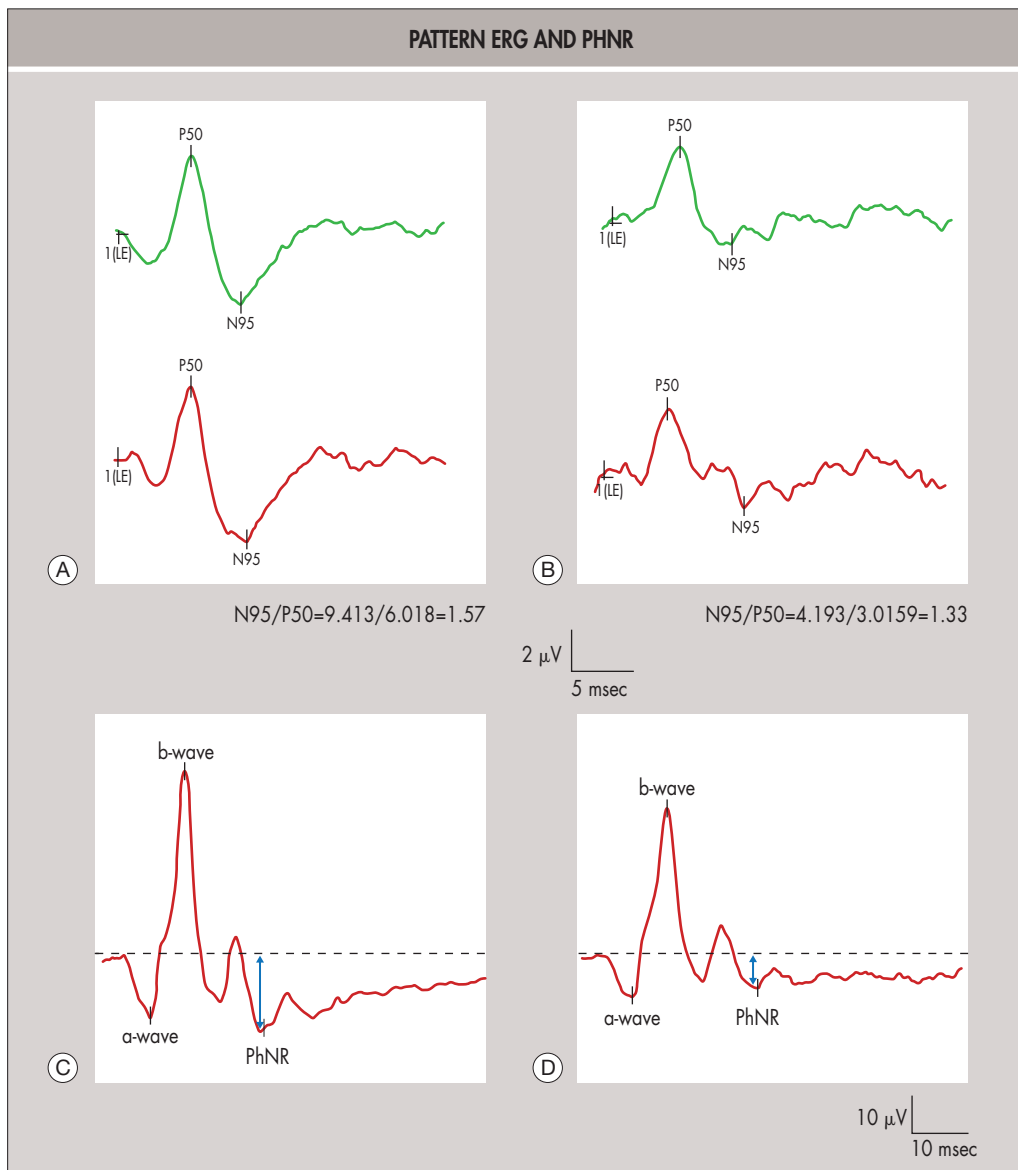

## OPTIC NERVE DISEASE

Direct assessment of ganglion cell function has become an area of great interest in neuro-ophthalmology.<sup>5</sup> It offers the ability to detect pre-perimetric glaucomatous optic nerve damage and to follow up patients to better understand and track the progression of optic nerve diseases, such as Leber's hereditary optic neuropathy (LHON) and idiopathic intracranial hypertension (IIH). There are two main methods of assessing the function of the retinal ganglion cells: (1) the N95 amplitude of p-ERG and (2) the amplitude of the photopic negative response (PhNR) of the ff-ERG (Fig. 9.27.4). The N95 component of p-ERG has been shown to be useful in patients with glaucoma, LHON and other optic neuropathies.<sup>6-8</sup> The PhNR

component of ff-ERG has also been shown to correspond with retinal ganglion cell function, and the amplitude has been found to correspond to the degree of optic nerve swelling in IIH.<sup>9</sup> By using a Ganzfeld stimulator, the PhNR is able to overcome the challenge of refractive correction and consistent fixation, which are required for p-ERG and can be challenging for patients who have central scotoma common in optic neuropathies.<sup>10</sup> But the main value of PhNR is that the retinal ganglion cell function is tested independent of the complexities posterior to the lamina cribrosa. Hence, oligodendrite dysfunction or lesions posterior to the optic chiasm will not affect the waveforms.

As more treatments are being developed for patients with optic neuropathies, the ability to detect pre-perimetric changes and to objectively follow up patients with profound vision loss is becoming more important. Electrophysiology, specifically PhNR and p-ERG, has an important role in objectively assessing the retinal ganglion cells and should prove useful in future clinical studies.

## PATTERN ERG AND PHNR

**Fig. 9.27.4 Pattern Electretinography (p-ERG) and Photopic Negative Response (PhNR) Recordings in Patients With Optic Neuropathies.** A normal p-ERG from the left eye (A) and abnormal p-ERG from the right eye (B) from a patient with a monocular optic neuropathy showing decreased N95 amplitude and N95/P50 ratios. A normal PhNR (C) and an abnormal PhNR (D) from a carrier and affected patient with Leber's hereditary optic neuropathy (LHON) demonstrating decreased PhNR amplitude in the affected patient.

# Epidemiology of Glaucoma

Osamah J. Saeedi, Sachin P. Kalarn, Pradeep Y. Ramulu, David S. Friedman

# 10.1

**Definition:** The distribution and types of glaucoma and the characteristic demographics of the disease.

### Key Features

- Glaucoma types:
  - Open angle:
    - Primary open angle glaucoma.
    - Secondary open angle glaucoma.
  - Angle closure:
    - Primary angle closure.
    - Primary angle closure suspects.
    - Primary angle closure glaucoma.
- Glaucoma suspect.
- Glaucoma prevalence and incidence.
- Glaucoma blindness.
- Risk factors for glaucoma:
  - Ocular.
  - Systemic.

### INTRODUCTION

Two major forms of glaucoma exist: open-angle glaucoma, in which aqueous humor has free access to the trabecular meshwork, and angle-closure glaucoma, in which access of the aqueous humor to the trabecular meshwork is obstructed. Both forms of glaucoma are characterized by a progressive optic neuropathy with visual field loss and characteristic structural changes, including thinning of the retinal nerve fiber layer and excavation of the optic nerve head.<sup>1</sup> Intraocular pressure (IOP) does not define glaucoma, and many with glaucoma have IOP measurements that overlap with individuals without glaucoma.

The nomenclature of angle-closure glaucoma has evolved over the past decade. The most commonly used system is that of Foster and colleagues, in which affected eyes are defined based on examination findings.<sup>2</sup> Primary angle-closure suspects (PACS) exhibit iridotrabecular contact (originally defined by  $\geq 270^\circ$ , but now more commonly defined as  $\geq 180^\circ$ ) without elevated IOP or peripheral anterior synechiae (PAS). Persons with primary angle closure (PAC) meet the criteria for PACS and have elevated IOP, PAS, or both. These individuals are believed to have suffered adverse sequelae of the iridotrabecular contact but do not have glaucoma. Finally, persons with primary angle-closure glaucoma (PACG) meet the criteria for PACS and have characteristic optic nerve damage. In addition, there is a group of patients who suffer an acute, symptomatic elevation of IOP in association with angle closure, referred to as acute angle closure (AAC).

Both open-angle and angle-closure glaucoma can occur secondary to other ocular conditions, though this chapter will mostly focus on primary open-angle glaucoma (POAG) and PACG. Although the optic neuropathies resulting from POAG and PACG may differ in some ways,<sup>3-6</sup> even more distinct is the epidemiology of these two conditions, which will be discussed separately later.

### PREVALENCE AND RATES OF ASSOCIATED BLINDNESS

Population-based studies are the gold standard for measuring the prevalence of eye diseases, and many have been conducted specifically for glaucoma, particularly in recent years. Table 10.1.1 outlines some major studies based on ethnicity.<sup>7-13</sup> Study techniques and definitions of glaucoma are not uniform across studies, prompting the publication of a suggested standardized definition of glaucoma to be used in prevalence surveys.<sup>2,14</sup>

A troublesome yet consistent finding across population-based studies is that a large portion of glaucoma remains undiagnosed. Population-based studies in United States, Ireland, and Australia reveal that 50% of those with glaucoma do not know they have it,<sup>8,15,16</sup> a percentage that rises to between 62% and 75% in Hispanic populations within the United States.<sup>10,17</sup> The rate of undiagnosed glaucoma is greater than 70% in Singapore<sup>18</sup> and greater than 90% in Japanese, Korean, Indian, and African populations.<sup>7,11,19,20</sup> That so many with a potentially blinding but treatable condition are unaware that they have the disease underscores the need for better screening strategies to identify those with glaucoma.

Glaucoma is a leading cause of blindness worldwide.<sup>21</sup> The frequency of bilateral blindness among persons with glaucoma varies across populations,<sup>7-9,11,17,22-26</sup> with substantial bilateral blindness from glaucoma observed in developing countries with poor access to eye care<sup>7,11</sup> and in populations where angle-closure glaucoma predominates (Table 10.1.2).<sup>9,22,23,24</sup> The rate of blindness may be reduced with improved glaucoma therapy. Notably, in Olmsted County, Minnesota, the rate of unilateral blindness in glaucoma has been cut in half, likely due to advances in glaucoma diagnostics and therapeutics.<sup>27</sup> When demographic projections with prevalence models for open-angle and angle-closure glaucoma are combined, it has been estimated that 112 million people worldwide will have glaucoma by 2040, with a heavier burden on Asian and African populations (Table 10.1.3).<sup>28</sup> Growth and aging of the world's population are expected to result in significant increases in these numbers. Although PACG remains less common than POAG, the numbers of individuals expected to be blind from both types of glaucoma is nearly equal given the higher morbidity of PACG.<sup>28</sup>

Cross-sectional associations seen in population-based studies help to define who is at risk for a disease, but they do not necessarily explain causality. That said, there are clear associations seen in the literature regarding POAG and PACG risk.

BOX 10.1.1 Primary Open-Angle Glaucoma Risk Factors

Demographic

- Race (African, Caribbean)
- Age
- Family history in parent or sibling

Ocular

- Intraocular pressure
- Nerve fiber layer thickness
- Myopia – central corneal thickness

Systemic

- Perfusion pressure

PRIMARY OPEN-ANGLE GLAUCOMA

The risk factors for POAG are summarized in Box 10.1.1.

Demographic Risk Factors for Primary Open-Angle Glaucoma

Race

Population-based studies demonstrate that POAG is most common in black Africans and African-descended persons living in the Caribbean and the United States (Fig. 10.1.1).<sup>7,24,29</sup> Seven percent of Afro-Caribbeans over the age of 40 living in Barbados had POAG, several times the prevalence of white and mixed-race individuals living in the same area.<sup>29</sup> A true racial difference in prevalence is also supported by a mixed-race study in Baltimore in which African Americans had nearly four times the prevalence of POAG than people of European descent living in the same neighborhoods.<sup>24</sup> POAG is also more prevalent in Hispanic populations compared with white populations, particularly in persons over the age of 60.<sup>10,17</sup> POAG appears to be more common in Chinese and Asian Indian populations than previously recorded, with comparable or slightly lower prevalence than seen in white populations.<sup>9,11,12,28,30–32</sup>

Age

The prevalence of POAG increases significantly with age, particularly for Hispanic people, who have the highest prevalence of POAG among

AGE-SPECIFIC PREVALENCE OF PRIMARY OPEN ANGLE GLAUCOMA (POAG) BY ETHNICITY

Fig. 10.1.1 Age-Specific Prevalence of Open-Angle Glaucoma by Ethnicity. (Adapted from Tham Y-C, Li X, Wong TY, et al. Global prevalence of glaucoma and projections of glaucoma burden through 2040: a systematic review and meta-analysis. *Ophthalmology* 2014;121:2081–90.)

all races for persons over 80 years of age (see Fig. 10.1.1).<sup>33</sup> A multiethnic population-based study in Baltimore showed tenfold increases in POAG prevalence for both white Americans and African Americans between the fifth and ninth decades of life.<sup>24</sup>

Gender

Although meta-analyses show a higher prevalence of POAG in men than in women,<sup>28,34,35</sup> this association is not consistent across all population-based studies. A few notable studies found no differences between men and women,<sup>8,12,24</sup> and still others show a higher prevalence in women.<sup>15,30</sup>

Family History

Persons in Baltimore who reported having a family member with glaucoma had a two- to fourfold increased risk of having glaucoma themselves. Knowledge of a sibling or parent with glaucoma conferred the greatest risk, whereas reporting a child with glaucoma showed no increased risk for glaucoma.<sup>36</sup> Those who were aware of their glaucoma were significantly more likely to report a family history than those who were unaware of their disease, suggesting that patients often learn about glaucoma in their family only after realizing that they themselves have it.<sup>36</sup>

A population-based case-control study from Holland more accurately assessed the importance of having a family member with POAG by directly examining first-degree relatives of patients with and without POAG. They found that siblings of patients with glaucoma were nine times more likely to have glaucoma than siblings of controls, suggesting that family history plays a greater role than what is shown by studies assessing family history using patient interviews.<sup>37</sup> In a high-risk Afro-Caribbean population, almost 30% of first-degree relatives of persons with POAG either had POAG, were POAG suspects, or had ocular hypertension, despite a relatively young median age of 47.<sup>38</sup> Given the substantial risk of POAG in siblings and children of glaucoma patients—and reports documenting that family members often are not informed by relatives<sup>36,39</sup>—it is important that patients with POAG be counseled to tell their siblings and children about their increased risk of having glaucoma.

The genetic basis of this familial transmission of glaucoma is largely unknown. Multiple genes responsible for POAG have been identified to date, although presumed disease-causing mutations are found in only a small percentage of POAG patients. These include myocilin,<sup>40</sup> optineurin,<sup>41</sup> WDR36, CYP11B1, and ASB10.<sup>41,42</sup> Notably, in an Australian disease registry study, 16% of advanced glaucoma patients with IOP above 21 at diagnosis, at least two affected relatives, and onset prior to age 50 had myocilin mutations.<sup>43</sup> Relatives of patients with myocilin mutations were then examined

**Fig. 10.1.2 Relative Risk of Primary Open-Angle Glaucoma (POAG) at Different Intraocular Pressures (IOPs).** (Adapted from Sommer A. Doyne Lecture. Glaucoma: facts and fancies. Eye 1996;10[Pt 3]:295–301.)

and 17% were diagnosed as glaucoma suspects,<sup>44</sup> indicating the potential utility of cascade genetic screening for glaucoma. The genetics of most glaucoma is likely complex, with disease resulting from the interactions of several genes that have yet to be identified.<sup>45</sup> No environmental factors (other than corticosteroid use<sup>46</sup>) have been associated with the development of POAG.

## Ocular Risk Factors for Primary Open-Angle Glaucoma

### Intraocular Pressure

IOP clearly plays an important role in the development of glaucoma and is one of the strongest known risk factors for the condition. Numerous studies across multiple ethnicities show an increased prevalence<sup>7,11,16</sup> and incidence<sup>47,48</sup> of glaucoma as IOP increases. Although the risk of glaucoma is substantial for persons with IOPs in the high 20s, data from virtually all population-based studies demonstrate that the risk for glaucoma increases steadily with increasing IOP, starting even with IOPs as low as 12 mm Hg (Fig. 10.1.2).<sup>7,11,16</sup>

The importance of IOP in causing glaucomatous damage is supported by the finding that in patients with asymmetric IOP, visual field loss is usually more severe in the eye with the higher IOP.<sup>49,50</sup> Furthermore, multiple studies show that lowering IOP in participants predisposed to glaucoma or with glaucoma decreases the rate of visual field loss.<sup>47,48,51</sup>

Despite the strong association between IOP and glaucoma, the large degree of overlap between intraocular pressures in people with and without glaucoma makes IOP a poor screening tool for glaucoma. Indeed, no IOP cutoff yields a good combination of sensitivity and specificity (Fig. 10.1.3).<sup>52</sup> In one study of Hispanic Americans in the United States, using an IOP of 22 mm Hg or higher to screen for glaucoma would miss 80% of POAG cases.<sup>10</sup>

### Optic Nerve Parameters

As optic nerve assessment is used to define glaucoma, it is not a true risk factor. Numerous quantifiable features of the optic nerve, including cup-to-disc ratio, rim area, and narrowest rim width, do a poor job of identifying glaucoma patients.<sup>52</sup> Optic nerve parameters sometimes fail to detect glaucoma because they fail to take into account disc size, with cup-to-disc ratios increasing as the size of the optic nerve head increases.<sup>53</sup> Confocal scanning laser microscopy with the Heidelberg Retinal Tomograph (HRT, Heidelberg Engineering, Dossenheim, Germany) as well as optical coherence tomography (OCT) have been used to determine optic nerve parameters. A Cochrane review of optic nerve head imaging found sensitivity and specificity of the vertical cup-to-disc ratio as determined by HRT to be 0.67 and 0.94, respectively. For OCT the sensitivity and specificity were similar, at 0.72 and 0.94.<sup>54</sup>

### Nerve Fiber Layer Imaging

A characteristic feature of POAG is thinning of the nerve fiber layer (NFL) as a result of ganglion cell death. This sometimes produces visible defects

**Fig. 10.1.3 Sensitivity and Specificity of Intraocular Pressure (IOP) in Detecting Glaucoma.** (Adapted from Tielsch JM, Katz J, Singh K, et al. A population-based evaluation of glaucoma screening: the Baltimore Eye Survey. Am J Epidemiol 1991;134:1102–10.)

in the NFL that can be observed at the slit lamp or photographically.<sup>55,56</sup> While clinical assessment of NFL may identify persons at higher risk of developing glaucoma,<sup>57,58</sup> they do not reliably distinguish patients with and without glaucoma.<sup>55,56</sup>

Thickness of the peripapillary nerve fiber layer has been measured by scanning laser polarimetry using the GDx VCC (Carl Zeiss Meditec, Inc.) and by OCT. The sensitivity and specificity of GDx for differentiating patients with glaucoma from those without glaucoma is 0.76 and 0.92, which is similar to that of OCT RNFL mean thickness, which has a sensitivity of 0.72 and specificity of 0.92.<sup>54,59–69</sup> Similarly, segmentation of the macular ganglion cell complex (GCC) or ganglion cell-inner plexiform layer (GC-IPL) via spectral-domain OCT can detect glaucoma with a similar sensitivity of 0.63 and specificity 0.93.<sup>54</sup>

### Myopia

Numerous clinic-based studies show an association between myopia and POAG, and population-based studies in different ethnic groups find rates of open-angle glaucoma two to four times higher for myopes.<sup>11,70,71</sup> The risk of glaucoma appears greatest in persons with higher degrees of myopia.<sup>11,70,72–75</sup> Myopia of greater than 6.00 diopters (D) confers a five times greater risk of glaucoma in East Asian populations.<sup>74</sup> Longer axial lengths and flatter corneas are also associated with a higher prevalence of POAG in Hispanic populations.<sup>76</sup>

### Peripapillary Atrophy

Population-based data from Hispanic people in Los Angeles showed that peripapillary atrophy was found in 83% of glaucomatous eyes, almost twice as often as ocular hypertensives in the same population.<sup>17</sup> However, no strict criteria were set forth to define peripapillary atrophy, and this finding was common among those without glaucoma. Prospective clinic-based studies have also demonstrated that a large zone of peripapillary atrophy is predictive of glaucomatous progression in eyes with pressures above 21 mm Hg.<sup>77,78</sup>

### Corneal Thickness and Hysteresis

Central corneal thickness was found to be an independent risk factor for progression to glaucoma in the Ocular Hypertension Treatment Study (OHTS),<sup>47</sup> although this association has not been found in East Asian populations.<sup>79,80</sup> There is conflicting evidence as to whether thin central corneal thickness is a risk factor for the presence or progression of glaucoma.<sup>81</sup> A number of studies assessed the association between glaucoma and corneal hysteresis, with some showing that patients with different forms of glaucoma have lower corneal hysteresis as compared to nonglaucomatous eyes

## GLAUCOMA PREVALENCE IS HIGHEST WITH LOW DIASTOLIS PERFUSION PRESSURE

**Fig. 10.1.4 Relationship Between Diastolic Perfusion Pressure (DPP) and the Predicted Prevalence of Open-Angle Glaucoma (OAG) in Participants of the Los Angeles Latino Eye Study.** (From Memarzadeh F, Ying-Lai M, Chung J, et al. Los Angeles Latino Eye Study Group. Blood pressure, perfusion pressure, and open-angle glaucoma: the Los Angeles Latino Eye Study. *Invest Ophthalmol Vis Sci* 2010;51:2872–7.)

and others showing no difference or even a higher corneal hysteresis value in glaucomatous eyes.<sup>82</sup>

## Systemic Risk Factors for Primary Open-Angle Glaucoma

### Diabetes

Two large meta-analyses suggested an increased risk of developing glaucoma in patients with diabetes.<sup>83,84</sup> Furthermore, duration of diabetes portends an increased risk of glaucoma, with a 5% yearly increased risk of glaucoma from diabetes diagnosis.<sup>84</sup>

### Hypertension

Higher systolic and diastolic blood pressures are associated with increased IOP.<sup>85,86</sup> In the Baltimore Eye Study, IOP was 1.5 mm Hg higher for patients with a systolic blood pressure over 160 mm Hg when compared to systolic blood pressures lower than 110 mm Hg.<sup>86</sup> The same study, however, did not find a statistically significant association between hypertension and glaucoma. Likewise, no association was seen between POAG and hypertension in South Indian participants<sup>11</sup> or Hispanic participants in the southwestern United States.<sup>10</sup>

The idea that insufficient perfusion of the optic nerve may contribute to glaucoma led the Baltimore Eye Study investigators to examine the relationship between POAG and diastolic perfusion pressure (defined as the difference between diastolic blood pressure and IOP). They found a significant increase in the rates of POAG for diastolic perfusion pressures under 50, with a greater than sixfold odds of having POAG noted when the diastolic perfusion pressure dipped below 30.<sup>7</sup> Similar findings were also reported for Caribbean and Hispanic populations (Fig. 10.1.4).<sup>10,87,88</sup> It is difficult to fully separate the influence of IOP from perfusion pressure epidemiologically.<sup>89</sup> There is no evidence to suggest that raising blood pressure delays the progression of glaucoma.<sup>90</sup>

### Cigarette Smoking, Alcohol Use, and Caffeine Consumption

Some clinic-based studies suggest an association between alcohol consumption and glaucoma. However, no differences in the prevalence of glaucoma were noted with mild, moderate, or heavy alcohol consumption in the Beaver Dam Eye Study,<sup>91</sup> nor in the nurses or health professionals study.<sup>92</sup> No definitive association was found with caffeine consumption either.<sup>93</sup> While a small increase in IOP was noted in smokers in the Australia Blue Mountains Eye Study even after adjusting for numerous other variables,<sup>94</sup> the prevalence of POAG has not been observed to vary between smokers and nonsmokers in other studies.<sup>10,91,95</sup>

## AGE-SPECIFIC PREVALENCE OF ACG BY ETHNICITY

**Fig. 10.1.5 Age-Specific Prevalence of Angle-Closure Glaucoma by Ethnicity.** (Adapted from Quigley HA, Broman AT. The number of people with glaucoma worldwide in 2010 and 2020. *Br J Ophthalmol* 2006;90:262–7.)

## BOX 10.1.2 Primary Angle-Closure Glaucoma Risk Factors

### Demographic

- Race (Chinese, Eskimo, Indian)
- Age
- Female gender
- Family history

### Ocular

- Anterior chamber depth
- Limbal anterior chamber depth
- Hyperopia
- Lens thickness
- Small radius of corneal curvature
- Lens vault

### Systemic

- None

## PRIMARY ANGLE-CLOSURE GLAUCOMA

The risk factors for PACG are summarized in Box 10.1.2.

## Demographic Risk Factors for Primary Angle-Closure Glaucoma

### Race

The highest reported prevalence of PACG is among Eskimo populations.<sup>50,96</sup> However, younger Eskimo participants in one recent study were significantly more myopic than previously reported, and this myopic shift may lead to lower rates of PACG in the future.<sup>97,98</sup> Additionally, numerous studies found a much higher prevalence of angle-closure glaucoma in East Asian populations when compared to black and white populations<sup>33</sup>—a difference almost certainly due to race. The prevalence of angle-closure glaucoma also increases substantially with age, particularly in Chinese individuals (Fig. 10.1.5).<sup>12,33</sup> Acute angle closure is presumed to be more common in Asian populations given the higher rate of PACG in cross-sectional samples from Asian countries and the demonstrated high proportion of angle closure in East Asian and Indian populations.<sup>23,99–101</sup> Researchers from Singapore assessed the rates of hospital admissions for AAC within different ethnic groups and found more than twice the rate for Chinese residents than for Indian and Malaysian residents.<sup>100</sup>

## Gender

Multiple studies performed in different ethnic backgrounds confirm that women are significantly more likely to get attacks of AAC and to develop PACG, with odds ratios ranging from 1.5 to 3.9.<sup>9,25,99,102</sup>

## Family History

An increased risk of PACG exists in family members of patients with PACG.<sup>103</sup> Work in Eskimo populations found strong familial determination of anterior chamber depth.<sup>96</sup> Siblings of Eskimo participants with PACG were also 3.5 times as likely to have PACG, suggesting that a familial predilection toward angle-closure glaucoma may result from heritable anatomic features.<sup>96</sup> Furthermore, in a South Indian population, siblings of individuals with angle closure have a greater than 1 in 3 risk of having some form of angle closure.<sup>104</sup>

The genes responsible for these familial associations had not been known until recently. While genes associated with nanophthalmos had been described previously,<sup>105</sup> more recent work using genome-wide association studies have identified multiple genetic loci associated with all forms of angle closure.<sup>106</sup>

## Ocular Risk Factors for Primary Angle-Closure Glaucoma

### Anterior Chamber Depth

Numerous studies demonstrate that the mean anterior chamber depth (ACD) in eyes with occludable angles or PACG is 0.3–1.0 mm shallower than in eyes without angle closure.<sup>5,99,100,107–109</sup> Eyes with AAC may have an even shallower mean ACD than PACG eyes.<sup>5,109</sup> In Chinese residents of Singapore, peripheral anterior synechiae became increasingly likely as ACD decreased, and the rate of glaucomatous optic neuropathy increased significantly when the ACD was less than 2 mm.<sup>102</sup> However, in South Indian and Taiwanese populations, no difference in ACD was noted between eyes with PACG and eyes of PACS, suggesting that greater shallowing of the anterior chamber does not necessarily imply worse disease.<sup>99,108</sup>

Shallower anterior chambers may partially account for the gender, age, and racial distribution of AAC and PACG. Women in multiple ethnic groups have been noted to have anterior chamber depths 0.1–0.2 mm shallower than men.<sup>99,103,110,111</sup> Population-based studies have also demonstrated that ACD decreases steadily with age, at least until the ninth decade.<sup>110,111</sup> Eskimo populations have the shallowest documented ACD.<sup>112</sup> The limited overlap of anterior chamber depths found in eyes with open angles and eyes with occludable angles<sup>96,99,108,113</sup> has led to the use of ultrasound and optical pachymetry to screen for occludable angles. Using these techniques, several groups have been able to identify persons with occludable angles (defined by gonioscopy) with sensitivities and specificities exceeding 80%.<sup>100,113</sup>

### Anterior Segment Optical Coherence Tomography

Use of anterior segment OCT (AS-OCT) has identified several risk factors for development of angle closure. Lens vault into the anterior chamber is correlated with ACD and independently associated with angle closure.<sup>114–116</sup> Anterior chamber width, area, and volume are other risk factors for angle closure identified by anterior segment OCT.<sup>117</sup>

A classification algorithm using these variables, in addition to iris thickness and iris area as determined from a single horizontal anterior segment OCT scan, identified gonioscopic angle closure more than 95% of the time in a Chinese population.<sup>118</sup> A separate prospective study of 342 mainly Chinese participants with gonioscopically open angles at baseline found that angle closure in at least one quadrant on baseline AS-OCT predicted development of gonioscopic angle closure at 4 years.<sup>119</sup>

### Limbal Anterior Chamber Depth

Although gonioscopy remains the gold standard for evaluating the anterior chamber angle, it can also be evaluated at the slit lamp through the van Herick method (or limbal anterior chamber depth, LACD), or modifications thereof.<sup>111</sup> Also, imaging techniques such as ultrasound biomicroscopy (UBM) and Scheimpflug photography suggest that compared to control eyes, eyes with AAC or PACG—and fellow eyes of patients with unilateral angle closure—have narrower anterior chamber angles and smaller angle opening distances (measured between the iris and posterior corneal surface at a defined distance from the scleral spur).<sup>109,120</sup>

Van Herick described how LACD can be estimated at the slit lamp by directing a slit beam at the temporal limbus with the light source offset 60° from the axis of the microscope and comparing the depth of anterior

chamber to the thickness of the cornea.<sup>121</sup> Work in Mongolia and Singapore showed that a LACD equal to 15% corneal thickness has a slightly better predictive value than using a cutoff of 25% (as initially proposed by van Herick).<sup>100,101</sup> In Chinese residents of Singapore, LACD measured at the slit lamp performed better as a screening test for detecting occludable angles or primary angle closure than did central anterior chamber depth, with both techniques significantly outperforming autorefractometry.<sup>100</sup> With gonioscopy as the gold standard, LACD has a sensitivity of 94% and specificity of 87% for detecting angle closure in a Chinese population.<sup>122</sup>

### Axial Length/Refractive Error

Work from multiple groups shows that axial length in eyes with PACG is 0.5–1.0 mm shorter than population-based controls,<sup>5,99,107–110,112</sup> with even shorter axial lengths found in AAC eyes.<sup>5,109</sup> These shorter axial lengths translate into more hyperopic refractions, with PACG eyes having a mean refractive error approximately 1.00 diopters (D) more hyperopic than eyes without PACG.<sup>5,99,107–110,112</sup> Hyperopia is a risk factor for PACG, and South Indians with hyperopia greater than 2.00 D developed PACG 3.7 times as often as those whose refractive error was on the myopic side of +2.00 D.<sup>22</sup>

White, black, Chinese, and South Indian women all have axial lengths about 0.5 mm shorter than their male counterparts.<sup>99,107</sup> Additionally, an Eskimo population with a high rate of ACG was noted to have a mean refraction 0.50 D more hyperopic than the average refraction for other races.<sup>112</sup> On the other hand, black, white, and Chinese populations have similar mean refractions despite highly dissimilar rates of PACG.<sup>107</sup> Hyperopia greater than 2.00 was actually found to be more common among individuals of European descent than among Chinese individuals in one study, although PACG rates were much higher among the Chinese group.<sup>107</sup>

In a South Indian population, axial length and refractive error were not risk factors for PACG when a multiple regression analysis was used, suggesting that these factors may predispose to PACG because of their association with other ocular biometric features, such as anterior chamber depth.<sup>99</sup> Indeed, strong correlations have been demonstrated between ACD and refractive errors.<sup>123</sup>

### Lens Thickness

Several studies confirm that eyes with PACG or AAC—and fellow eyes in patients with unilateral AAC—have lenses 0.2–0.6 mm thicker than controls,<sup>5,108–110</sup> although work from South India showed very similar lens thickness in PACG eyes, eyes with occludable angles, and controls.<sup>99</sup> Groups that are more susceptible to angle closure tend to have thicker lenses. Mean lens thickness in Eskimo populations is 0.3–0.4 mm greater than that of white and black populations, whereas mean lens thickness in Chinese populations is 0.1–0.2 mm thicker than in white and black populations.<sup>112</sup> Lens thickness increases with age and may be an important explanation for the progressive shallowing of the anterior chamber and increased prevalence of PACG observed in older age groups.<sup>112</sup>

### Radius of Corneal Curvature

A smaller radius of corneal curvature results in a more crowded anterior chamber, which is associated with a higher risk of angle closure. Most studies have found that eyes with PACG and fellow eyes of patients with unilateral AAC have a slightly smaller average corneal radius of curvature than controls,<sup>5,108,120</sup> although one study noted a similar mean corneal radius of curvature in control eyes and eyes with PACG.<sup>107</sup> Little racial variation in corneal curvature exists, although women of all races have a smaller mean corneal radius of curvature compared to men.<sup>107</sup>

TABLE 10.1.4 Prevalence of Pseudo-Exfoliation in Different Population-Based Studies

Study	Country	Age Group Studied	Prevalence of Pseudo-Exfoliation Noted Per 100 Persons
Middle-Norway <sup>126</sup>	Norway	65+	16.9
Thessaloniki <sup>125</sup>	Greece	60+	11.9
Blue Mountains <sup>15</sup>	Australia	50+	2.2
Roscommon <sup>8</sup>	Ireland	50+	1.3
Aravind <sup>11</sup>	India	40+	0.4
Kongwa <sup>7</sup>	Tanzania	40+	<0.1
Proyecto VER <sup>10</sup>	United States	40+	<0.1
Chinese <sup>9</sup>	Singapore	40–79	<0.1

TABLE 10.1.5 Prevalence of Glaucoma Suspects in Population Studies

Study (Ethnic Group)	Type of Glaucoma	Criteria to Identify Glaucoma Suspects	Prevalence Per 100 Persons	Age (Range)
Roscommon <sup>8</sup> (European white population)	Open-angle	IOP of 22 or greater <i>and</i> CD of 0.5 or greater <i>and</i> no visual field changes	1.1	50+
Andhra Pradesh <sup>29</sup> (South Indian population)	Open-angle	Disc criteria for glaucoma <i>and</i> absence of visual field changes	1.1	40+
Barbados <sup>28</sup> (African Caribbean population)	Open-angle	Disc criteria without field changes <i>or</i> visual field changes not meeting disc criteria	3.6	40–86
Framingham <sup>34</sup> (US white population)	Open-angle	IOP 22 or greater <i>or</i> CD 0.5 or greater <i>or</i> CD asymmetry (≥0.2 difference between eyes) <i>or</i> IOP asymmetry (≥3 mm Hg difference with IOP of ≥16)	7.9	52–85
Chennai <sup>97</sup> (South Indian population)	Angle closure	Posterior trabecular meshwork not visible 180° <i>and</i> IOP 22 or greater	6.3	40+
Hövsjö <sup>122</sup> (Mongolian population)	Angle-closure	Pigmented trabecular meshwork not visible 270° without indentation	6.4	40+
Tanjong Pagar <sup>98</sup> (Singapore Chinese population)	Angle-closure	Posterior trabecular meshwork not visible 180°	6.5	40–79

CD, Cup-to-disc ratio; IOP, intraocular pressure.

Systemic Risk Factors for Primary Angle-Closure Glaucoma

No systemic factors are known to contribute to the development of PACG, and a population-based study in South India found no associations of PACG with diabetes or hypertension.<sup>99</sup>

SECONDARY GLAUCOMAS

Population-based studies with low rates of pseudo-exfoliation report rates of secondary glaucoma (resulting from pseudo-exfoliation, vein occlusions, diabetes, uveitis, trauma, and other causes) between 0.15% and 0.7%, with secondary glaucoma comprising 4%–18% of all glaucoma cases.<sup>7,8,15,124,125</sup> Whether pseudo-exfoliation glaucoma is a primary or secondary form of glaucoma depends on definition, and researchers vary in how they present their data. Secondary glaucomas other than pseudo-exfoliation occur infrequently. In populations where pseudo-exfoliation is found, its prevalence varies substantially, with the highest rates found in Greek and Scandinavian populations (Table 10.1.4).<sup>7–11,15,126–128</sup> People with pseudo-exfoliation have substantially higher mean IOPs, a significantly higher risk of developing glaucoma, and a higher rate of glaucoma progression.<sup>8,11,15,126</sup>

OCULAR HYPERTENSION

Ocular hypertension is a condition in which the IOP is higher than would be expected based on population statistics for normal IOP. In populations of European descent the traditional cutoff has been 22 mm Hg because this number is outside two standard deviations from the mean.<sup>129</sup> However, some Asian populations have a lower mean IOP, and a pressure above 19 mm Hg would be considered elevated in these individuals. Many now think of an IOP of 24 mm Hg or higher as consistent with ocular hypertension, as was required for enrollment in the OHTS.<sup>47</sup>

The percentage of people with an IOP elevated to 22 mm Hg or greater in the absence of glaucoma ranges from 1%–4% in most population-based studies (see Table 10.1.1). In the OHTS trial, the rate of developing either disc or field loss without eye-pressure-lowering treatment was about 10% at 5 years,<sup>47</sup> similar to the 5-year incidence of glaucoma noted in mostly untreated ocular hypertensives from a population-based study in Barbados.<sup>130</sup> Persons with certain risk factors (large baseline cup-to-disc ratio, thin corneas, older age, higher IOP, and subtle decrements in the baseline visual field) have much higher rates of glaucoma development, whereas those lacking these risk factors are very unlikely to develop glaucoma even if untreated.<sup>47</sup>

GLAUCOMA SUSPECTS

Some individuals present with concerning optic nerve appearances and either borderline visual field loss or normal visual fields. Physicians typically monitor these persons without treatment, although certain individuals with this presentation will be treated. Studies use a wide variety of definitions to identify angle closure suspects and open-angle glaucoma suspects, reporting a prevalence of 1%–8% for open-angle glaucoma suspects<sup>8,22,29,35</sup> and 6%–7% for angle-closure suspects (Table 10.1.5).<sup>23,99,100</sup>

# Screening for Glaucoma

Brian C. Stagg, Paul P. Lee, Joshua D. Stein

## 10.2

**Definition:** Ideal disease screening identifies all individuals with a given disease (100% sensitivity) and excludes all those without it (100% specificity).

### Key Features

- Cost-effective screening for any disease requires that the disease is progressive, can be reliably detected prior to clinically significant effects on patients, and that interventions can retard, stop, or reverse damage.
- Screening of general populations for the current case definition of glaucoma is not currently deemed cost effective, but current office-based detection is cost effective from a societal perspective. Using a stepped approach targeting higher prevalence populations may also be cost effective.
- Additional information about the natural history and impact of glaucoma on patient functioning prior to the onset of detectable visual field loss is critically needed to assess the desirability of screening for glaucoma without visual field loss (currently defined as “early” or “pre-perimetric” glaucoma).

## INTRODUCTION

The glaucomas are a diverse group of eye conditions sharing the common feature of pathological optic neuropathy without (the open-angle variants)<sup>1</sup> or with (the closed-angle variants)<sup>2</sup> visible occlusion of the trabecular meshwork (the drainage angle in the anterior chamber). Because these represent two distinct groups of entities with fundamentally different mechanisms of initial dysfunction at two distinct ocular anatomic areas, comprehensive screening for all glaucomas requires at minimum two distinct approaches. This chapter uses a general approach to the understanding of screening programs that is applicable to both approaches. However, specific comments and an analysis of screening studies are limited to the more common, open-angle forms (for such aspects of closed-angle screening, see Friedman et al.<sup>3</sup>).

## HISTORICAL REVIEW

### Screening Programs

Screening should ideally identify every person with a given condition (100% sensitivity) while clearing everyone without it (100% specificity). In reality, however, no such ideal test exists. Thus, a reasonable balance between sensitivity and specificity is sought. The definition of reasonable balance may be arbitrary, achieved through consensus over time, or based on empirical analyses of test performance (for example, by using a C-statistic or assessing the area under receiver-operating characteristic [ROC] curves) and associated costs of screening and cost per true case identified.<sup>4</sup> To be a practical reality, screening tests must detect an important health problem and be simple and inexpensive to perform, requiring, ideally, the assistance of lay persons or midlevel or technician-level providers, and must allow for rapid testing in the community setting.<sup>5–8</sup> It should be performed only when adequate resources exist to care for any disease detected and do so in a cost-effective manner.<sup>7,9</sup> Such techniques are desirable because enhancing current office-based case detection, while cost effective,<sup>10</sup> may overtax the available supply of optometrists and ophthalmologists in the future (assuming that current care patterns continue).<sup>11</sup>

### Prior Glaucoma Screening Efforts

Glaucoma screening traditionally relied on intraocular pressure (IOP) measurements based on a now outdated case definition of glaucoma requiring an elevated IOP (except for so-called normal-tension glaucoma), together with the presence of visual field defects and optic nerve or nerve fiber layer (NFL) abnormalities. Performance of IOP measurements alone has proven unacceptably poor for glaucoma screening.<sup>5,9,12,13</sup>

A large 5-year study conducted in Sweden showed that patients with glaucoma were identified earlier through community-based screening compared to routine clinical practice.<sup>14</sup> However, to date, no randomized, controlled trial has assessed population screening for glaucoma, particularly for the detection of structural optic nerve abnormalities alone.<sup>15,16</sup> Several studies have evaluated the use of various screening parameters, such as numerous automated visual field screening and suprathreshold strategies, optic nerve head cup-to-disc ratios, optic nerve neuroretinal rim indicators, and risk factor analyses (involving variables such as age, sex, race, or ocular and other medical history).<sup>13,17</sup> All such indicators have proven inadequate as single screening tools. Significant interest remains in finding an approach to screen for glaucoma, given the relatively high incidence of glaucoma in certain populations<sup>18</sup> and considering that at least half of all persons (and up to 90% in less developed economies) with glaucoma are unaware that they have it.<sup>1,18,19</sup>

### Current Definition of Open-Angle Glaucoma

The results of studies prior to 2000 need to be read cautiously, however, in light of the current definition of primary open-angle glaucoma (POAG), first promulgated by the American Academy of Ophthalmology (AAO) in 1996<sup>1</sup>: “a chronic, progressive optic neuropathy in which there is a characteristic acquired atrophy of the optic nerve and loss of retinal ganglion cells and their axons.” Early or mild—also referred to as “pre-perimetric”—glaucoma is characterized by optic nerve abnormalities with normal visual fields.<sup>1</sup> This definition is an explicit recognition of the limitations of current visual function testing, since over 30% of the optic nerve fibers are lost before current functional testing can differentiate patients with and without glaucoma.<sup>19–22</sup> Thus, visual field defects are no longer part of the case definition of glaucoma; those with visual field loss are referred to as “perimetric” glaucoma and are staged as “moderate” or “severe.” Moderate glaucoma is defined as visual field abnormalities in one hemifield, not within 5° of fixation, whereas severe glaucoma involves visual field abnormalities in both hemifields or loss within 5° of fixation.<sup>1</sup>

The current definition has inherent limitations due to the need for the optic nerve structures to demonstrate “acquired” changes, making case diagnoses, especially of pre-perimetric glaucoma, problematic with assessments at a single point in time. Such uncertainty in case definition will decrease the test performance of approaches to screen for pre-perimetric glaucoma using this conceptual framework due to misclassification in both directions. As such, suggestions have been made to define glaucoma purely as “perimetric” glaucoma on the basis of the population distribution of optic nerve characteristics (2.5% on a one-sided basis) and a reproducible visual field defect<sup>19,21</sup>—or potentially even on the basis of the optic nerve characteristic alone to encompass the most likely pre-perimetric cases. This “instrument”-based approach has also been proposed to leverage new insights on anatomic structures revealed by spectral-domain ocular coherence tomography (SD-OCT). Analyses of structures using SD-OCT demonstrate that existing techniques of assessment do not accurately differentiate neural from other tissues in many patients; initial studies demonstrate significantly better performance than current indices as expressed in likelihood ratios.<sup>23</sup> Thus, future definitions of OAG based on “instrument criteria” may be one potential approach of defining glaucoma.

Just like current systemic hypertension is diagnosed via a blood pressure measurement, glaucoma may be diagnosed on structural or functional characteristics—understanding that as with systemic hypertension, not everyone with the diagnosis will go on to lose vision.

## PURPOSE OF THE TEST

The purpose of a glaucoma-screening test is to detect those with disease so that they can then be treated before significant reduction in visual function occurs. The current definition raises two sets of fundamental questions. The first is a threshold inquiry of whether screening should seek to identify pre-perimetric glaucoma prior to the onset of visual field loss or if it should seek to identify those who have moderate glaucoma, with the onset of reproducible visual field loss on automated perimetry.<sup>19</sup> This has become a critical question due to the repeated findings of the US Preventive Services Task Force (USPTF)<sup>24</sup> and other expert bodies that screening for pre-perimetric or even mild perimetric glaucoma is not supported by the available scientific evidence.<sup>9,16,19,24–26</sup> Among the key factors cited by USPTF for ratings of “uncertain” are the lack of evidence in three key areas:

- Those without reproducible visual field defects using standard automated perimetry have significant functional or patient-centered limitations.
- Delay in diagnosis until later in the disease would have a measurable impact on patient outcomes prior to death.
- The benefits of early detection outweigh the harms resulting from screening activities.<sup>24</sup>

In contrast to earlier assessments, there is strong evidence supporting screening for at least moderate perimetric POAG that meets the WHO criteria<sup>7,9</sup> for screening for diseases. Indeed, the Global Association of International Glaucoma Societies Committee on Screening for Open Angle Glaucoma noted that the case for POAG screening has been strengthened considerably in recent years and stated that the “evidence weakly supports justification for community glaucoma screening on a limited scale and for specific purposes.”<sup>27</sup> First, therapy for glaucoma is sufficient to slow or prevent progressive loss of vision as measured by visual fields, based on the results of several randomized controlled trials.<sup>19,27,28</sup> Second, visual field loss and the amount of loss is associated with meaningful decreases in patient functioning, as measured by patient self-report of function, observed or measured performance by patients at home or in office or laboratory settings, and rates of significant mishaps such as falls or motor vehicle accidents or self-restrictions.<sup>29–39</sup> Third, results from randomized controlled trials such as the Collaborative Initial Glaucoma Treatment Study (CIGTS) provide meaningful data about the performance characteristics of standard automated perimetry, so that protocols can be established to optimize the performance of perimetry.<sup>40</sup> Fourth, community-based exams will detect glaucoma with visual field loss on standard automated perimetry among those without prior knowledge of glaucoma earlier than routine patient-driven, office-based detection.<sup>14</sup> Fifth, knowledge of the effect of suboptimal vision on patients’ function has increased considerably in recent years.

For patients with “trouble seeing,” the quality of life (QOL) impact is commensurate with that of several major systemic illnesses.<sup>41–43</sup> Yet glaucoma patients traditionally have been thought not to have noticeable vision problems until relatively late in the disease course. A prospective case-control study reported that patients with glaucoma had significantly lower general functional status than those without glaucoma,<sup>29</sup> although results of other studies contradict this finding.<sup>30,31</sup> However, Hyman et al. found that under  $-4.15$  mean deviation (MD), there was no significant effect of glaucoma on QOL as measured by the Visual Function Questionnaire (VFQ).<sup>35</sup> Patients with MD scores of  $-4.16$  to  $-19.08$  had clinically and statistically meaningful VFQ deficits. Economic modeling has shown that detection and treatment of moderate stages of glaucoma of around  $-4.0$  dB of mean deviation loss in the better eye is significantly cost effective, ranging from \$28,000 to \$48,000 per quality-adjusted life year (QALY).<sup>10</sup>

What is lacking is consistent evidence that detection of visual field loss prior to the threshold of  $-4$  dB loss in the better eye is beneficial to patients. While some studies indicate that unilateral visual field loss is associated with a significant increase in falls among the elderly (including those without glaucoma),<sup>44</sup> most papers indicate that bilateral visual field loss or loss in the better eye (especially in those with glaucoma alone as a cause) is needed before significant decrements are detected, even using innovative techniques such as global positioning system (GPS) devices and accelerometer tracking of physical activity.<sup>45</sup>

This lack of data raises a second set of two important questions:

- What are the likelihood and rate of progressive loss of function in persons with early and minimal moderate glaucoma (i.e., those with only optic nerve or retinal NFL loss or visual field loss less than 4 dB of mean deviation in the better eye or on binocular testing)?
- Is treatment success over a person’s life in terms of preservation of visual function compromised if the therapy is initiated later in the disease course?

Answering these inquiries is key to understanding the value and usefulness of screening even high-risk patient populations.

Results of trials provide important information. Estimates of the likelihood of progression from early optic nerve loss to subsequent additional loss depend on the stage of disease.<sup>46–48</sup> Among untreated persons with elevated IOP in the Ocular Hypertension Treatment Study (OHTS), 9% had progression of optic nerve changes or visual field loss over 6 years.<sup>49</sup> Risk factors for incremental progression included an increased cup-to-disc ratio, indicating the possibility of subtle prior glaucomatous damage (early glaucoma, by definition). For those with manifest glaucoma (including early visual field loss), the Early Manifest Glaucoma Trial showed that 62% of untreated patients had worsening of their visual field over 5 years.<sup>49,50</sup> On the basis of a meta-analysis of these and other data, Maier and colleagues concluded that reducing IOP “in patients with ocular hypertension or manifest glaucoma is beneficial in reducing the risk of visual field loss in the long term.”<sup>51</sup> On a population basis, Czudowska et al. estimated that the 10-year incidence of developing glaucomatous visual field loss was 1.9% among those age 55–59, rising to 6.4% among those age 80 or older in the Rotterdam Eye Study.<sup>52</sup>

The second question is whether early treatment is related to a better outcome over the course of the disease. A study from Olmstead County, Minnesota, looked at the rates of glaucoma progression to blindness in patients undergoing filtration surgery.<sup>53</sup> One of the key findings from this study was that patients who had more severe visual field loss at presentation had an increased risk of blindness following surgery. This suggests that intervening earlier in the course of the disease, prior to the development of significant field loss, is beneficial. Considering that most patients will demonstrate disease worsening during their lifetimes despite therapy, if patients are identified earlier through screening, they may not progress to blindness or significant visual impairment. Thus, the importance, value, and timing of screening for glaucoma has become more positive, but it remains an open question pending additional information on the functional impact of early visual loss and on whether later treatment can effectively halt progression of vision loss. Modeling of a lifetime of therapy starting at different levels of severity of disease on the rates of levels of visual loss to endpoints less severe than WHO standards of visual impairment or blindness would provide important information in this regard. Understanding the impact at rates of visual loss less than impairment or blindness is important because population-based studies indicate that visual functioning is linearly related to visual measures such as acuity, contrast sensitivity and visual field.<sup>54,55</sup>

## UTILITY OF THE TEST AND INTERPRETATION OF RESULTS

The Prevent Blindness America Glaucoma Advisory Committee has promulgated criteria for minimum performance characteristics for adjunctive devices used in glaucoma screening, including 95% specificity (98% preferable) and at least 85% sensitivity for moderate-to-severe visual field defects.<sup>8</sup> The desirability of these or any other criteria for specificity or sensitivity must be evaluated in light of the effect of such performance on the probability of correctly identifying a person with glaucoma by applying Bayes’ theorem. As Table 10.2.1 shows, such a screening test performance,

**TABLE 10.2.1 Application of Bayes’ Theorem to Screening Test Performance**

	General Population Age 40+		Family Members/Nerve Head Only	
	Glaucoma	No Glaucoma	Glaucoma	No Glaucoma
Prior probability	0.02	0.98	0.09	0.91
Test performance	0.85	(1.00–0.95)	0.85	(1.00–0.95)
Posterior probability	0.017	0.049	0.0765	0.0455
Positive test (%)	26	74	63	37

TABLE 10.2.2 Application of Bayes’ Theorem to Enhanced Screening Test Performance

		General Population Age 40+		Family Members/Nerve Head Only	
		Glaucoma	No Glaucoma	Glaucoma	No Glaucoma
Increased sensitivity	Prior probability	0.02	0.98	0.09	0.91
	Test performance	1.00	(1.00–0.95)	1.00	(1.00–0.95)
	Posterior probability	0.02	0.049	0.09	0.0455
	Positive test (%)	29	71	66	34
Increased specificity	Prior probability	0.02	0.98	0.09	0.91
	Test performance	0.85	(1.00–0.98)	0.85	(1.00–0.98)
	Posterior probability	0.017	0.030	0.0765	0.0182
	Positive test (%)	46	54	81	19

given the low prior probability of glaucoma in the general population older than 40 years of age (using the old case definition), still results in three false positives for every true positive. However, if the prior probability could be raised to, for example, 8%–10% (as with testing family members only or using the current definition of glaucoma with only optic nerve head findings required), test performance at these criteria would be enhanced significantly and yield two true cases for every false positive identified.

As Table 10.2.2 shows, using a screening test with 100% sensitivity barely affects the posterior probability that a positive test correctly identifies a patient as having glaucoma. Thus, changing the sensitivity of the test beyond 85% has much less effect than the application of methods to alter the prior probability of having glaucoma in the populations being screened. However, an increase in the specificity of the test to 98%, as suggested by PBA, improves test performance the most. An example of the limitations of programs to identify patients in populations with relatively low prevalence is seen in the low yield even among African Americans age 50–59, where 58 persons would need to be screened to detect one case of glaucoma and 875 to prevent one case of blindness, with a technique (frequency-doubling technology [FDT] screening) with a modeled 92% sensitivity and 94% specificity.<sup>56</sup> Therefore, approaches that increase the prior probability of having glaucoma and methods using tests with better specificity may be efficient means of screening for glaucoma, provided adequate sensitivity exists.<sup>57</sup>

Because the comparison of tests with different sensitivities and specificities at different cutoff or threshold levels is difficult to evaluate fully, the use of ROC curves or the c-statistic is essential in comparing the test performances of different glaucoma screening tools.<sup>58,59</sup> Superior tests or methods can be readily distinguished from others through comparison of the areas under the curves and the graphic displays of such curves. Similarly, c-statistics can demonstrate the ability of tests to discriminate those with and without disease. Thus future comparisons of screening methods should use ROC curves, provide c-statistics, or perform similar analyses.

PROCEDURE

The goal (detection of early versus moderate glaucoma) and target population (general population or higher prevalence subpopulation) of the screening program will strongly influence the choice of methods and the procedures used. For the detection of those with moderate glaucoma with visual field loss of more than 4 dB of mean deviation loss in the better eye, either standard automated perimetry or a proxy for such perimetry will provide a definitional test. As noted in the CIGTS study, however, many patients with initially qualifying visual field losses did not have such losses confirmed on repeat testing.<sup>39</sup> Screening even with automated perimetry for moderate glaucoma will require confirmatory testing or evaluations, especially for those with relatively minimal visual field loss. Further, patients seen in a general population will have other potential causes for visual field loss. Therefore, as Francis et al. reported about the Los Angeles Latino Eye Study, “no single screening parameter is useful for glaucoma screening. However, a combination of vertical cup to disc ratio, Humphrey Visual Field, and IOP provides the best balance of sensitivity/specificity [0.92/0.92]...”<sup>60</sup>

In the case of detecting glaucoma before the onset of visual field loss, screening for glaucoma can potentially be simplified to an evaluation of the results of optic nerve assessments based on the current case definition of glaucoma as an optic neuropathy and the demonstration that optic nerve fiber loss may be identified before visual field loss occurs.<sup>46,61</sup> With the definition of what optic nerve or NFL findings constitute “characteristic” loss, the current AAO preferred practice pattern contains one possible

set of indicators for screening: thinning or notching of the rim, progressive change (cupping), or NFL defects.<sup>1</sup> Screening programs that determine that one or more of these findings exist have, by definition, screened appropriately for glaucoma.

Optic nerve and retinal NFL imaging is used to determine structural loss. The rapid advances in imaging techniques over the past decade—including confocal scanning laser tomography (CSLT), scanning laser polarimetry (SLP), optical coherence tomography (OCT), and retinal thickness analysis—have shown significant promise for glaucoma screening. More recently, the higher definition obtained by SD-OCT has enabled investigators to better anatomically define the structures of the optic nerve and optic nerve head, resulting in a measure with a reported 79% sensitivity and 95% specificity.<sup>62</sup> Many authors have published reviews of these and other techniques in the last few years.<sup>63–66</sup>

For example, a comparative study concluded that when used alone, CSLT, SLP, and OCT summary reports “did not provide sensitivities and specificities that justify implementing them as primary population screening tools for early to moderate glaucoma.”<sup>67</sup> However, other investigators have noted that use of the summary parameters from multiple imaging devices together can improve the specificity considerably.<sup>68</sup> A major disadvantage of these technologies is the need for a skilled operator. (For a review of the advantages and disadvantages of these technologies, see Michelson and Groh.<sup>69</sup>) Conventional photographic imaging of the optic disc by an experienced examiner remains the most sensitive early detection method<sup>70</sup>; however, these new imaging technologies hold potential for glaucoma screening, particularly in combination with functional testing such as FDT. Assessing these new imaging technologies is difficult because the accuracy of a test can be determined only by comparing it with a “gold standard” reference test, yet no single test available today can definitively diagnose glaucoma. In evaluating the optic nerve, uncertainty and inaccuracy related to screening arise from the inherent variability between observers in the assessment of the same clinical situation (interobserver variability), with the same observer at different points in time (intraobserver variability), and with the accuracy of the method used to measure the optic nerve head or NFL. Although in some studies experts have had relatively high levels of interobserver agreement and intraobserver consistency for certain indicators, other investigations have observed significant variation or noted that levels of agreement decreased with less experienced observers and the method used.<sup>71–73</sup> In OHTS, which used a rigorous quality assurance protocol, trained technicians’ repeated gradings of the baseline horizontal cup-to-disc ratio from optic disc stereophotographs were highly reproducible.<sup>74</sup> However, the OHTS investigators noted that these findings are nongeneralizable to routine clinical practice. If agreement rates for the presence or absence of glaucoma are substituted as equivalents for sensitivity and specificity, likely posterior probabilities can be generated for an accurate screening result for glaucoma status by using these technological techniques. In contrast, even highly experienced and skilled glaucoma specialists can accurately identify only 60% of worsening optic discs in a masked fashion relative to the temporal time relationship of the photos taken.<sup>75</sup>

COMPLICATIONS

The risks associated with screening for glaucoma fall into two categories. The first is the risk of false identification of the true ocular status. Persons falsely assured that they are disease-free risk experiencing subsequent undetected visual loss. In contrast, persons falsely identified as having glaucoma may experience concomitant anxiety and incur expenses before their true status can be clarified, or, worse, they may subsequently undergo

uncalled-for treatment, thus needlessly being put at risk for therapy-related complications, such as cataract formation.<sup>24,76</sup>

The second area of risk is related to the nature of the examination itself. For screening efforts involving proper assessment of the optic nerve or retinal NFL, the necessary use of dilating agents may precipitate an angle-closure attack in as many as 1 in 333 persons.<sup>77</sup>

## ALTERNATIVE TESTS

### Analysis of Tests

Before the current definition of glaucoma was established, investigators had reported several promising methods for identifying individuals with visual field loss on standard suprathreshold static perimetry or kinetic perimetry (Goldmann), including scotopic sensitivity testing,<sup>78</sup> Henson visual field analysis and Damato campimetry (and oculokinetic perimetry),<sup>79,80</sup> peripheral color contrast,<sup>81</sup> and simultaneous interocular brightness sense testing.<sup>82</sup> All these techniques are designed to screen for moderate glaucoma. Such techniques, however, have not been demonstrated to be beneficial in screening for pre-perimetric glaucoma.

In the past two decades significant interest and investigation has been devoted to determining the utility of several new techniques in detecting glaucoma prior to standard automated perimetry (SAP) and thus expand detection to what would have otherwise been pre-perimetric glaucoma. These techniques include FDT perimetry, short wavelength automated perimetry (SWAP), Swedish Interactive Threshold Algorithm (SITA) perimetry,<sup>83,84</sup> multifocal electroretinography (mERG), and multifocal visual evoked potential (mVEP).<sup>64–66</sup>

Of these techniques, FDT has shown the greatest promise as a practical means of glaucoma screening to detect perimetric glaucoma and potentially pre-perimetric glaucoma. In a prospective study by Cello and colleagues,<sup>85</sup> FDT demonstrated 85% sensitivity and 90% specificity for detecting early glaucomatous visual field loss and 96% sensitivity and 96% specificity for detecting moderate glaucomatous visual field loss. These data suggest that FDT would meet PBA's minimum performance characteristics. Moreover, other studies have found FDT to be effective in screening for moderate glaucomatous damage.<sup>86,87</sup> FDT is performed significantly more rapidly than SAP or SWAP, making it well suited for screening. With FDT, the reported average testing time per eye is less than 2 minutes (instrument time) with glaucoma patients and less than 30 seconds with healthy controls.<sup>87,88</sup> In addition, FDT perimetry is relatively inexpensive and portable, requires no special training for the examiner or patient, and can be used in adults with reading disabilities.<sup>89,90</sup> Furthermore, FDT may have less intertest and intratest variability than conventional perimetry does.<sup>91</sup> However, FDT has yielded a substantial proportion of false-positive results in patients with diabetes mellitus and a significantly increased rate of false positives in patients' left eye compared with the right.<sup>92,93</sup> While promising, the American Academy of Ophthalmology's Ophthalmic Technology Assessment (OTA) indicated that "the screening FDT protocol can detect most eyes with visual field defects on SAP with an acceptable level of specificity. The data are also consistent with the concept that some of these apparent false-positive results actually may represent the detection of glaucoma damage by FDT earlier than by SAP."<sup>64</sup>

Other perimetric techniques also show promise but have disadvantages that make them impractical for screening in their current forms. For example, SWAP, or blue–yellow perimetry, may detect field defects earlier than can white-on-white standard threshold automated perimetry,<sup>94</sup> but SWAP—even with the SITA version—requires expensive standardized automated perimetry equipment and trained personnel, with the same or greater issues of intertest reliability.<sup>64,95</sup>

Electrophysiology, which is the use of minimally invasive electrical equipment to measure the function of the retina and optic nerve, has the potential to provide objective detection of early glaucoma.<sup>96,97</sup> Pattern electroretinography (pERG) is perhaps the best studied form of electroretinography in glaucoma.<sup>97</sup> PERG detects glaucomatous vision loss up to 4 years earlier than standard visual fields, with a sensitivity of 75% and a specificity of 76%.<sup>98</sup> In a study from Australia, measurement of mVEPs compared favorably with traditional visual fields for detection of glaucoma.<sup>99</sup> mVEP measures the localized electrical responses from the occipital cortex for the central visual field. The sensitivity and specificity of mVEP were 80.6% and 89.2%, whereas sensitivity and specificity for visual fields were 81.9% and 79.5%.<sup>99</sup> However, no electrophysiological test for glaucoma is in widespread use at this point, in large part because of the lack of strong evidence that it is superior to traditional methods and the need for specialized equipment and technical skills.<sup>96,97</sup>

If screening for the earliest stage of glaucoma—that of optic nerve fiber loss alone—is desired, these methods will require extensive and lengthy follow-up to determine if individuals detected with abnormalities eventually do worsen. However, if screening is found efficient or cost effective only for those with visual field loss, methods predicated on field loss should receive further attention and evaluation as potential screening techniques.

## Telemedicine and Glaucoma Screening

Advances in structural and functional technology to detect patients with glaucoma—along with improved computer and information transfer capabilities—have made glaucoma screening in remote communities possible through the use of telemedicine.<sup>100,101</sup> A recent systematic review by Thomas et al. thoroughly summarizes 45 studies that evaluated the use of telemedicine for glaucoma screening. The pooled estimates of sensitivity and specificity for telemedicine detection of glaucoma were 83.2% and 79.0%. Telemedicine was more sensitive but less specific than in-person examination, by their analysis. However, further randomized research is necessary as all 45 studies evaluated were observational. They also found that the mean cost for every case of glaucoma detected by telemedicine was US\$1098.67.<sup>100</sup>

### Marker Testing for Glaucoma

In the past 15 years genetic analysis of families with POAG has identified numerous genetic loci that may be involved in the pathogenesis of the disease.<sup>102–108</sup> Although tests for genes such as *TIGR*/myocilin have been developed, these tests have limited usefulness<sup>109</sup> because they only detect less than 5% of people who will later develop POAG in adulthood.<sup>110–112</sup> However, genetic testing for glaucoma may become a reality.<sup>113</sup> Moreover, Challa and colleagues showed that patients expressed relatively positive attitudes toward hypothetical genetic testing for glaucoma.<sup>114</sup> Thus, genetic linkage analysis, genome-wide analysis, and other techniques offer the promise that patients might be screened for glaucoma on a genetic basis through analysis of peripheral blood or other specimens in the future, although current technology is not sufficient.

Evidence has also grown on the potential role that the immune system and inflammation may play in glaucoma pathogenesis.<sup>115</sup> To the extent that autoimmune or other inflammatory mechanisms are implicated in glaucoma, testing for specific or general biomarkers of inflammation or autoimmunity may also play a role in screening or diagnosing glaucoma.

Again, however, the performance of these techniques may vary depending on the case definition of glaucoma used. Similarly, the utility of such screening also presupposes that effective treatments exist and that the cost–benefit ratio of such screening, based in large part on the test's performance characteristics, justifies screening a given population.

## FUTURE DIRECTION OF GLAUCOMA SCREENING

A critically important study from Australia found that optometrists and ophthalmologists frequently failed to diagnose early to moderate (98% moderate) glaucoma among patients with pertinent risk factors, visual field changes, and optic nerve damage. These findings underscore the need for diagnostically precise approaches and potentially technological devices in the accurate identification of persons with glaucoma.<sup>116</sup> The first step in improving the health of our population is therefore to more accurately detect glaucoma among those who already access the care system and see an optometrist or ophthalmologist.

Automated image processing techniques such as deep learning, artificial neural networks, and fuzzy logic may eventually decrease our reliance on human evaluation for glaucoma screening.<sup>117,118</sup> Deep learning has successfully been employed in screening for diabetic retinopathy.<sup>119,120</sup> These methods could potentially make glaucoma screening less expensive and more efficient. However, none of these are of sufficient accuracy at this point for clinical use.<sup>118</sup>

Additional interventions may lie in developing approaches or devices that can identify persons with early or moderate glaucoma who will develop further visual loss, particularly at a rapid pace.<sup>21,121</sup> Identifying patients earlier in the course of the disease who never go on to develop visual loss to the extent that it affects health-related QOL is not prudent. Such a strategy will result in our subjecting many individuals to costly medications that have side effects with little benefit, at least as we understand the impact of glaucoma today. Alternatively, waiting until an individual already has significant functional damage from glaucoma before detecting and treating such patients is also potentially of serious concern

even if treatment is initiated, since such patients may continue to suffer additional loss of visual function, as noted in the Olmstead County data.<sup>53</sup>

New approaches to screening are likely to arise as more is learned about the pathophysiology of glaucoma and the impact lower amounts of nerve tissue loss has on patients. In the future, we may adopt an instrument-based definition of glaucoma, use a combination of tools either collectively or in sequence, or combine a range of factors to target those who would be most likely to lose vision without early detection and treatment. For example, applying Bayes' theorem would suggest that the population to be screened should have a higher prevalence or prior probability than the general population level of 2% of those over the age of 40. Using factors from the ocular or medical history, blood testing, diagnostic testing, or examination features could easily increase prevalence to 10% or higher. This enriched population would then have a single (or combination) test applied to more accurately detect affected individuals.

Finally, for any screening program to be effective, integrated healthcare delivery systems must be in place to ensure that those individuals who are identified to be at risk for vision loss from glaucoma receive appropriate treatment.<sup>122</sup> Otherwise, spending resources to simply identify individuals at risk through screening efforts will not improve outcomes, as the patients will not receive the treatment necessary to delay or prevent damage and loss of vision.

# Mechanisms of Glaucoma

Jeffrey L. Goldberg, Martin Wax, Abbot (Abe) Clark, Mortimer M. Civan

## 10.3

**Definition:** Glaucoma occurs through a number of mechanisms, usually related to intraocular pressure that is too high for the optic nerve to withstand. High intraocular pressure is almost always due to poor aqueous outflow (low outflow facility). Mechanical damage, impaired optic nerve blood flow, withdrawal of neurotrophic factors, and production of neurotoxic molecules in the optic nerve have each been proposed as possible mechanisms of optic nerve damage in glaucoma.

### Key Features

- Aqueous humor physiology in health and disease.
- Aqueous humor pathophysiology in glaucoma.
- Mechanisms of glaucomatous optic neuropathy.

### INTRODUCTION

Glaucomatous optic neuropathy is the second leading cause of irreversible blindness in the United States<sup>1</sup> and is characterized by the demise of retinal ganglion cells (RGCs) and their axons that can lead to impaired visual function and blindness. Clinically glaucoma is characterized by its progressive optic atrophy with a typical excavation of the nerve head that lacks prominent pallor of the neuroretinal rim and a progressive loss of peripheral visual sensitivity in the early stages of the disease, which may ultimately progress and impair central visual acuity.<sup>2</sup> Although glaucomatous optic neuropathy is typically observed in open- or closed-angle glaucoma and associated with elevated intraocular pressure (IOP), a high percentage of patients (20%–30% in Western countries, >50% in Japan) have findings that are anatomically identical but without IOP elevation above population norms.<sup>3,4</sup>

Glaucoma is unique among the ophthalmic diseases because its clinical management and the underlying pathophysiology requires knowledge of ocular structures that span both the anterior and posterior segment. This chapter will describe the basic mechanisms that underlie aqueous production and outflow, optic nerve axon damage and degeneration, and RGC death in glaucomatous optic neuropathy.

Although IOP was removed as an integral part of the definition of glaucoma, for most forms of the disease, IOP is a major risk factor for both the development<sup>5</sup> and the progression<sup>6,7</sup> of glaucoma. Even in normal-tension glaucoma in which IOP does not exceed 21 mm Hg, IOP remains a risk factor for progressive optic nerve damage.<sup>8</sup> Elevated IOP associated with most forms of glaucoma is associated with increased resistance to aqueous humor outflow, while the rate of aqueous humor formation is not different from that in nonglaucomatous individuals.

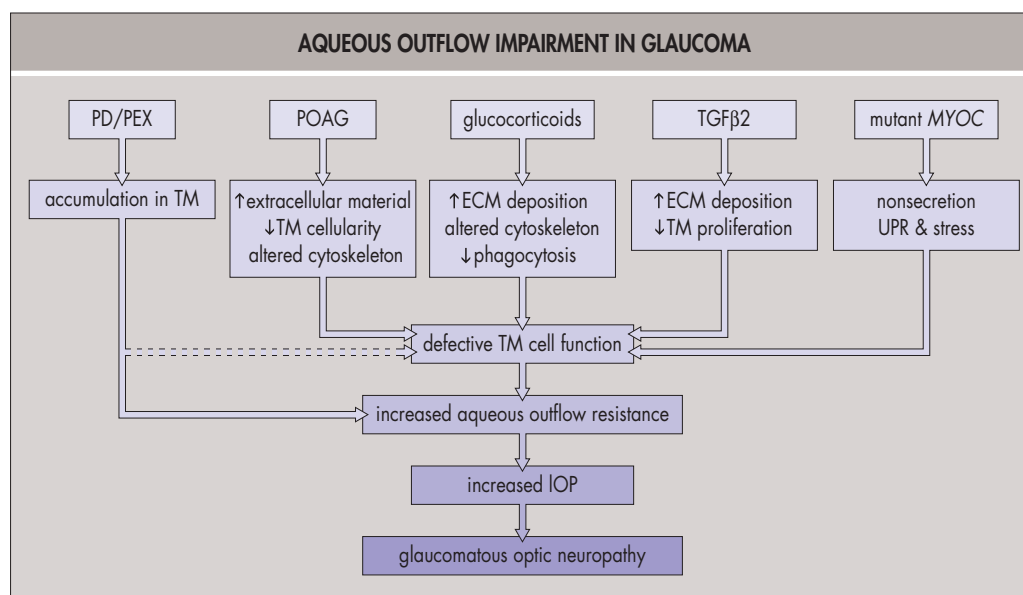

The causes of impaired aqueous humor outflow are different for the different subtypes of glaucoma (Fig. 10.3.1). In angle-closure glaucoma, the outflow pathway is blocked by physical occlusion of the outflow pathway by the iris. In the particulate forms of open-angle glaucoma, including pigmentary glaucoma, pseudoexfoliation glaucoma, and uveitic glaucoma, particulate matter “clogs” the trabecular meshwork (TM) and impairs aqueous outflow. Defects in development of the outflow pathway are responsible for most forms of congenital glaucoma. In primary open-angle glaucoma (POAG) and corticosteroid-induced glaucoma, there are no clinically observable findings that can explain the increased outflow resistance responsible for elevated IOP.

### PHYSIOLOGY OF AQUEOUS PRODUCTION

Secretion of aqueous humor sustains metabolism of the avascular anterior segment, ensures inflation of the globe, and may play other roles.<sup>9</sup> The composition of the aqueous humor is largely similar to that of protein-free plasma with several exceptions, including a much higher concentration of ascorbic acid in the aqueous humor. Understanding the physiology of aqueous production relates to reducing its rate, a major strategy for lowering IOP in glaucoma.

### Structural and Functional Overview of Aqueous Humor Formation

Aqueous humor is secreted by the ciliary epithelium. The structure is unique in juxtaposing the apical surfaces of its two component layers (Fig. 10.3.2). The basolateral surfaces of the pigmented ciliary epithelial (PE)

**Fig. 10.3.1 Mechanisms of Aqueous Outflow Impairment in Glaucoma.** A variety of glaucomatous insults to the trabecular meshwork can lead to elevated IOP and the development of glaucomatous optic neuropathy. ECM, Extracellular matrix; IOP, intraocular pressure; MYOC, myocilin gene; PD, pigmentary dispersion; PEX, pseudoexfoliation; POAG, primary open-angle glaucoma; TGF-β2, transforming growth factor-beta-2; TM, trabecular meshwork; UPR, unfolded protein response.

**Fig. 10.3.2** Mechanisms of unidirectional secretory pathways (A) and potential reabsorptive pathways (B) across the ciliary epithelium.

and nonpigmented ciliary epithelial (NPE) cells face the stroma of the ciliary processes and aqueous humor, respectively. Gap junctions link cells within and between the two cell layers,<sup>10</sup> such that the epithelium is conventionally considered a functional syncytium. Ablation of ciliary epithelial cells through laser diode or endocyclophotocoagulation has risen in utility as an approach to decrease IOP.

Aqueous humor secretion essentially depends on transfer of solute, primarily NaCl, from the stroma to the posterior chamber of the eye. This transfer establishes a small osmotic gradient driving water passively into the aqueous humor. Secretion proceeds in three steps: uptake of solute and water from the stroma by PE cells, fluid transfer through gap junctions linking PE to the NPE cells, and release of solute and water by NPE cells into the aqueous humor. These steps involve an expanding number of transport proteins, and the energy required for the secretion is derived from adenosine triphosphate (ATP) utilized by  $\text{Na}^+$ ,  $\text{K}^+$ -activated ATPase located predominantly at the aqueous humor surface of the NPE cells.

## Three Steps in Aqueous Secretion

### *Ion and Fluid Uptake From the Stroma*

The PE cells can take up NaCl from the stroma by two major electroneutral processes (Fig. 10.3.2A). One entry mode for  $\text{Na}^+$  from the stroma into the PE cells is through an  $\text{Na}^+/\text{H}^+$  counter-exchanger (the NHE-1 antiporter), in exchange for  $\text{H}^+$  leaving the cells. In parallel,  $\text{Cl}^-$  can be taken up by the PE cells in exchange for  $\text{HCO}_3^-$  release through an anion counter-exchanger (the AE2 antiporter). Cytosolic carbonic anhydrase II stimulates this NaCl uptake in two ways, increasing the rate of delivery of  $\text{H}^+$  and  $\text{HCO}_3^-$  to the two antiports and directly activating them both (see Fig. 10.3.2A). The clinical reduction in secretion and IOP produced by carbonic anhydrase inhibitors is likely mediated by reducing turnover of NHE-1 and AE2 antiports.

The second mode of NaCl uptake from the stroma by the PE cells is through a  $\text{Na}^+ - \text{K}^+ - 2\text{Cl}^-$  cotransporter (symport). The rate of uptake depends on the concentration gradient for the three ions transported and is particularly dependent on the concentration ratio of external to intracellular  $\text{Cl}^-$ .<sup>11</sup> The diuretic bumetanide blocks the symport and inhibits  $\text{Cl}^-$  secretion and aqueous humor formation in vitro but not (by itself) in vivo, presumably because of compensatory uptake through the paired antiports.

The pathways for water uptake are not as well studied. Water likely crosses the stromal surface of the PE cells through channels but not through known aquaporin water channels. Alternatively, water might simply diffuse across the PE cell membranes, for example, but membranes with low contents of sphingomyelin and cholesterol display relatively high water permeability.<sup>12</sup>

### Fluid Transfer Through Gap Junctions

The gap junctions linking PE to NPE cells are more numerous than those linking cells within the PE and NPE layers.<sup>10</sup> These PE–NPE gap junctions are formed of connexin proteins (Cx43 and Cx40), with Cx43 likely playing a dominant role.<sup>13,14</sup> The connexins comprising the links between adjacent NPE cells are different (Cx26 and Cx31), and evidence for these connexins within the PE-cell layer is still lacking.<sup>15</sup> The PE–NPE gap junctions are not only more numerous but possibly more robust to experimental perturbation<sup>16</sup> than the PE–PE and NPE–NPE gap junctions. This suggests that aqueous humor is fundamentally formed by parallel couplets of PE–NPE cells.<sup>16</sup> Interruption of the PE–NPE gap junctions with heptanol or octanol markedly reduces ionic current and net  $\text{Cl}^-$  movement across the ciliary epithelium.<sup>17</sup> However, these inhibitors are too nonselective to be clinically relevant.

### Fluid Transfer Into the Aqueous Humor

The final step in secretion is the transport of solute and water across the basolateral membranes of the NPE cells into the aqueous humor (Fig. 10.3.2A).  $\text{Na}^+$  is pumped by  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase against an electrical gradient.  $\text{Cl}^-$  is released down its electrochemical gradient through  $\text{Cl}^-$  channels into the aqueous humor.<sup>17</sup> Water is released passively through aquaporin AQP1 and AQP4 channels in response to the osmotic gradient established by net solute transport.  $\text{HCO}_3^-$  likely exits both through  $\text{Cl}^-/\text{HCO}_3^-$  exchangers<sup>18,19</sup> and  $\text{Cl}^-$  channels.<sup>19,20</sup>  $\text{Cl}^-$ -channel activity at the aqueous surface likely limits the rate of secretion.<sup>17</sup>

Other transporters involved in net secretion have been identified, and many pharmacological agents, hormones, and signaling pathways clearly modulate secretion,<sup>17</sup> but their physiological significance is unclear.

### Regulation of Net Aqueous Humor Formation

Much of our understanding of the transport mechanisms underlying inflow is derived from in vitro measurements. Some of these insights have been validated in living animals. The mouse is advantageous for study because of the greater similarity of its conventional outflow pathway to the human than those of other commonly studied nonprimate models. The availability of transgenic animals and advances in imaging modalities also enhance the strength of the mouse model in addressing clinically relevant issues.<sup>21,22</sup>

The diurnal rate of aqueous humor inflow varies substantially and is 2.5 times higher during waking than during nocturnal hours. Any putative transporter limiting the rate of inflow would also be expected to undergo substantial changes in activity. Among the factors reported to stimulate NPE-cell  $\text{Cl}^-$  channel activity<sup>17</sup> are cell swelling, stimulation of  $\text{A}_3$ -subtype adenosine receptors, inhibition of protein kinase C (PKC) activity, and production of cyclic-3', 5'-adenosine monophosphate (cAMP). Modulation of inflow by  $\text{A}_3$ -subtype adenosine receptors is of physiological,

pathophysiological, and pharmacological interest. These receptors are overexpressed in the NPE cells from patients with the pseudoexfoliation syndrome.<sup>23</sup> In vitro electrophysiological and volumetric measurements have suggested that stimulation of A<sub>3</sub> adenosine receptors increases Cl<sup>-</sup> and fluid release by NPE cells and that A<sub>3</sub> antagonists block those effects. Adenosine is physiologically delivered to the receptors by autocrine/paracrine release of ATP through large-diameter pannexin-1 and connexin hemichannels and vesicular release.<sup>24</sup> The ATP is subsequently converted to adenosine by ecto-ATPases. Modulation of adenosine receptor activity pharmacologically may decrease IOP.

The precise regulatory roles of second-messenger pathways and the multiplicity of the transporters targeted complicate formulation of a comprehensive model of inflow regulation. For example, beta-blockers are clinically used to lower inflow, presumably by reducing cAMP. However cAMP exerts multiple actions producing opposing effects on secretion.<sup>17</sup> Increasing evidence now suggests that compartmentation of second messengers such as cAMP and Ca<sup>2+</sup> is essential to their signaling function.<sup>25,26</sup>

## Conclusions and Future Directions

In summary, aqueous humor is formed by transferring solute from stroma to the posterior chamber, establishing an osmotic gradient, with water moving in response to that gradient. Many of the proteins underlying fluid transport have been identified, but their integrated actions and regulation are less well understood. Pharmacological or surgical (e.g., by laser ablation) inhibition of inflow is a common powerful strategy for lowering IOP in glaucoma. Clarification of the roles of second-messenger compartmentation and functional topography may facilitate development of novel strategies for slowing aqueous production and thereby lowering IOP in glaucomatous patients.

## THE AQUEOUS HUMOR OUTFLOW PATHWAY

Aqueous humor exits the eye via two pathways. The trabecular pathway is considered the primary, pressure-dependent pathway, whereas the uveoscleral pathway is considered the secondary, pressure-independent pathway, although the pressure dependence/independence of these pathways is not absolute.<sup>27</sup> Anatomically, the trabecular pathway consists of the uveal and corneoscleral TM, the juxtacanalicular tissue (JCT), and Schlemm's canal (SC). The major site of aqueous outflow resistance in a normal eye is thought to reside mainly in the JCT and inner wall of SC.<sup>28</sup> In the uveoscleral outflow pathway, aqueous humor exits the eye through the iris root through the interstitial spaces between the ciliary muscle bundles into the superchoroidal space, where it is absorbed into the venous system.

What are the regulators of normal aqueous outflow? This is an important question, and recent progress in our understanding of TM cell biology suggests that TM cells themselves have a "rheostat" for IOP control. The recently discovered cilium on TM cells harbors compartmented, subcellular signaling properties that directly sense IOP through mechanotransduction and feedback to regulate IOP.<sup>29</sup> This has generated important targets for considering new approaches to IOP control, including cell therapy (discussed later).

## Pathology of the Glaucomatous Outflow Pathway

There are age-related changes to both the trabecular and the uveoscleral outflow pathways. On the relatively less well-studied uveoscleral pathway, glaucomatous eyes show ultrastructural evidence of increased extracellular material deposition.<sup>18</sup> Prostaglandin analogues, now the primary first-line pharmacological class of antihypertensive medications, lower IOP and enhance uveoscleral outflow in association with stimulation of ciliary muscle matrix metalloproteinases (MMPs) and degradation of ciliary muscle and scleral extracellular matrix (ECM) components.<sup>30</sup>

The TM has received much more study. There is decreased TM cellularity with age<sup>31-33</sup> and increased extracellular deposition in the TM<sup>34</sup> associated with age-dependent decreased aqueous outflow.<sup>35,36</sup> TM tissues from POAG donor eyes are significantly "stiffer" (i.e., less elastic) compared to TM tissues from age-matched control eyes.<sup>37</sup> Decreased TM tissue cellularity and alterations in extracellular material are observed in POAG eyes compared to age-matched controls.<sup>38</sup> Ultrastructural assessment of numerous eyes from patients with glaucoma showed a thickening of trabecular beams and elastic tendons, increased plaque material, and lattice collagen in the TM.<sup>39,40</sup> The ECM does play an important role in regulating aqueous humor outflow in the TM. Perfusion of cultured human anterior segments with MMPs or agents that activate TM MMPs,

which degrade ECM proteins in the TM, enhances aqueous outflow,<sup>41,42</sup> while perfusion with MMP inhibitors increases outflow resistance.<sup>41</sup> There also appears to be enhanced deposition of the extracellular matrix adhesive glycoprotein fibronectin in the TM of glaucomatous eyes.<sup>43,44</sup> The composition of TM glycosaminoglycans (GAGs) is altered in the glaucomatous TM, with decreased hyaluronan and increased chondroitin sulfate and GAGase-resistant proteoglycans.<sup>45</sup> Several groups reported increased expression of transforming growth factor-beta-2 (TGF-β2) in the aqueous humor of POAG patients,<sup>46,47</sup> and this cytokine has been shown to elevate IOP in perfusion cultured human eyes<sup>48,49</sup> and in transduced mouse eyes,<sup>50</sup> promote ECM deposition in cultured TM cells,<sup>49,51</sup> and enhance covalent cross-linking of ECM proteins via tissue transglutaminase<sup>51</sup> and lysyl oxidase (LOX).<sup>52</sup>

The TM cytoskeleton also regulates aqueous humor outflow. Agents that disrupt TM cell actin microfilaments, including cytochalasin, latrunculin, and various kinase inhibitors including Rho kinase (ROCK) inhibitors now under active clinical investigation, also increase aqueous humor outflow.<sup>53</sup> In contrast, glucocorticoids elevate IOP by decreasing aqueous humor outflow and reorganize the TM microfilaments into cross-linked actin networks<sup>54,55</sup> associated with decreased TM cell functions such as proliferation, migration, and phagocytosis.<sup>54</sup>

Corticosteroid-induced glaucoma mimics POAG in many ways, including the clinical manifestations of elevated pressure and glaucomatous damage to the optic nerve head.<sup>56</sup> Elevated IOP in both diseases is due to increased aqueous humor outflow resistance and is associated with similar biochemical and morphological changes to the TM. Similar changes in the TM extracellular matrix, including increased deposition of fibronectin,<sup>57,58</sup> GAG profiles,<sup>59,60</sup> and reorganization of the actin cytoskeleton<sup>54,55</sup> occur in the glucocorticoid-treated TM.<sup>61</sup> However, a unique ultrastructural feature of corticosteroid-induced glaucoma is the presence of "fingerprint-like" extracellular deposits in the TM.<sup>62</sup> Not all individuals treated with glucocorticoids develop elevated IOP. However, those who do (i.e., corticosteroid responders) have a significantly greater risk of developing POAG in their lifetime,<sup>63</sup> and the majority of POAG patients are corticosteroid responders.<sup>64,65</sup> Differences in glucocorticoid sensitivity between normal and glaucomatous individuals may be explained by an alternative splice variant of the glucocorticoid receptor GR-beta, which acts as a dominant negative regulator of glucocorticoid activity. Glaucomatous TM cells have lower levels of GR-beta compared to nonglaucomatous cells, making these glaucomatous TM cells more responsive to glucocorticoids.<sup>66</sup> This mechanism may also be responsible for differences in corticosteroid responsiveness among normal individuals.

The reduction in TM cellularity may also play a role in the pathophysiology of glaucomatous IOP elevation. There are both age- and glaucoma-dependent loss of TM cells.<sup>31,33,38</sup> Cultured TM cells have been used effectively to provide experimental support for the hypothesis that their biology determines aqueous outflow and thus IOP.<sup>67</sup> A subset of TM cells behave like TM progenitor or stem cells, can be expanded in three-dimensional cultures, and express markers and gene expression profiles consistent with TM stem cells.<sup>68</sup> Exploring TM cell transplant as an approach to enhance outflow and lower IOP is in preclinical testing.

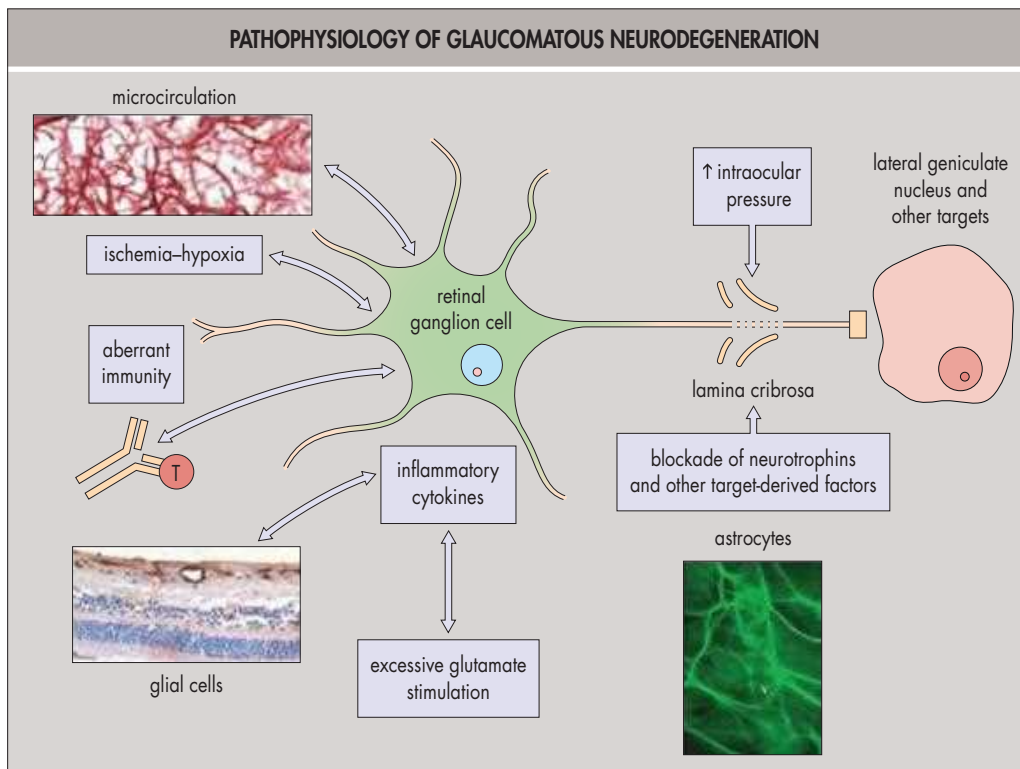

## Conclusions and Future Directions

Molecular genetic, genomic, and proteomic techniques increasingly are being used to better understand glaucomatous damage to the aqueous outflow pathways, which leads to increased outflow resistance and elevated IOP. Advances in genetics and in the cell and molecular biology of aqueous outflow regulation will undoubtedly identify new therapeutic targets and the development of new therapeutic agents that will intervene in the disease process(es) and provide better future therapy targeting IOP for patients with glaucoma.

## PATHOPHYSIOLOGY OF GLAUCOMATOUS OPTIC NEUROPATHY

Although the clinical course and features of glaucomatous optic neuropathy are well characterized, the cellular and molecular mechanisms that underlie the pathogenesis of the degeneration of optic nerve axons and death of RGCs are incompletely understood. Decades of observation have revealed that there are variations in the appearance of the optic nerve and in the progression of visual field damage that occur within the spectrum of glaucoma patients. For example, patients with normal pressure glaucoma are commonly found to have visual field defects that are steeper (in

**Fig. 10.3.3 Mechanisms Contributing to Pathophysiology of Glaucomatous Neurodegeneration.** Intraocular pressure can cause blockade at the lamina cribrosa of axonal protein transport, causing neuronal retinal ganglion cell death by trophic insufficiency. Other implicated factors include local ischemia-hypoxia, excessive stimulation of the glutamatergic system, alterations in glial cells or astrocytes, and aberrant immunity. Reprinted with permission from Elsevier (Weinreb RN, Khaw PT. Primary open-angle glaucoma. *Lancet* 2004;363:1711–20.)

the gradient of light sensitivity loss across retinal area), deeper (increased severity of scotoma), and closer to fixation than their elevated IOP patient counterparts.<sup>69,70</sup> In addition, their optic nerve cupping occurs focally and segmentally, at least in the early stage of neuropathy. It is unlikely that a single pathophysiological mechanism accounts for either the initiation or progression of glaucomatous damage in all afflicted patients. The putative mechanisms that underlie glaucomatous optic neuropathy are most likely multiple (Fig. 10.3.3); each mechanism may have variable impact on the phenotype seen clinically. These mechanisms may also interact, and they likely involve multiple cellular elements in the retina, although their commonly observed clinical effect is RGC preservation or demise.<sup>71</sup>

## Glaucomatous Neuropathy Occurs in Response to Increased Cell Stress Conditions

Causes of glaucomatous optic neuropathy may be disease specific, a pathological response to excessive physiological stress in neurons or glial cells of the retina or optic nerve, or an accelerated process of normal aging that individually or together lead to axon damage and RGC death. These stress conditions may be generalized as IOP-dependent or -independent, although evidence suggests that most eyes with glaucoma are likely affected by pathogenic mechanisms involving both components.

Hypotheses for glaucomatous pathophysiology have been longstanding, but other than for the contribution of IOP to disease progression, remain without conclusive proof. Two of the oldest theories still active today were proposed in the same year, 1858, by individuals who are recognized for their substantial contributions even today.<sup>72,73</sup> Heinrich Müller, a German anatomist who was soon to prove conclusively that phototransduction occurred in rods and cones and whose namesake describes the principal retinal glial cell, was the first to suggest that mechanical compression due to elevated IOP was the cause of glaucomatous damage. Eduard von Jaeger, the ophthalmologist who was the father of clinical perimetry and who first described the use of iridectomy for the treatment of angle-closure glaucoma, proposed that eyes with poor vascular supply to the optic nerve head were predisposed to glaucoma. He further suggested that optic nerve head ischemia could occur in patients with either elevated or normal IOP.

## Disrupted Axon Transport

The mechanical theory of elevated IOP as the cause of glaucoma has been greatly enhanced in recent times. In the late 1960s and early 1970s, blockade of axoplasmic flow was demonstrated in experimental glaucoma in animals.<sup>74–76</sup> This provided a long-sought physiological aspect to the mechanical theory in which optic nerve cupping and excavation were

thought to be the primary observable sequelae of elevated IOP. In the 1990s, it was found that trophic factors, including brain-derived neurotrophic factor (BDNF), are retrogradely transported from the RGC axonal terminals to the cell bodies of the neurons and that trophic factors are essential to RGC survival. Thus, IOP-dependent RGC axon compression was shown to reduce axonal transport trophic factors causing RGC death by trophic insufficiency, as was first demonstrated in experimental glaucoma in rats<sup>77,78</sup> and later in primates.<sup>79</sup>

Recently, animal models of glaucoma have further linked the progressive visual decline in glaucoma to axonal degeneration. Degeneration is detected early where RGC axons terminate in the superior colliculus (RGCs' primary target in the rodent brain), and transport deficits progress in a retrograde fashion toward the retina.<sup>80</sup> Susceptibility to damage is dependent on increasing age, as smaller IOP elevations lead to RGC damage in older animals.<sup>81</sup>

## Vascular Hypothesis

Similarly, considerable support remains for a vascular theory in which chronic or intermittent hypoxia or ischemia is thought to contribute to glaucomatous optic neuropathy.<sup>82–85</sup> Immunohistochemistry studies in postmortem human glaucomatous eyes found that the oxygen-regulated transcription activator hypoxia-inducible factor-1 alpha (HIF-1 $\alpha$ ) was upregulated in retinal locations that were highly concordant with the location of the visual field defects recorded in these eyes.<sup>86</sup> In addition, endothelin-induced chronic ischemia in monkey eyes elicits optic nerve damage that is non-IOP dependent and results in axon loss that is similar to the damage observed in human glaucoma.<sup>87</sup>

## Excitotoxicity Due to Excessive Glutamate

The discovery that excessive and perhaps extrasynaptic concentrations of the neurotransmitter glutamate act as a potent neurotoxin led to the term excitotoxicity. The vitreous humor of glaucomatous monkeys and humans contain elevated glutamate,<sup>88</sup> which initially led to the hypothesis that excitotoxicity could be a significant pathogenic mechanism in glaucoma.<sup>89</sup> However, initial studies were not reliably reproduced,<sup>90,91</sup> and the result from the negative outcome of the phase III clinical trial of memantine, a selective glutamate antagonist,<sup>92</sup> have together decreased enthusiasm for this hypothesis.

## Oxidative Stress and Free Radical Damage

The role of oxidative stress, free radical damage, and mitochondrial function has been studied in various models of glaucoma and in human

disease. There is a compelling body of evidence to suggest that mitochondrial dysfunction can trigger apoptosis signaling via activation of the mitochondrial permeability transition pore complex, which is a key regulator of oxidative stress-induced apoptotic cell death.<sup>92</sup> Evidence for the central role of mitochondrial dysfunction in animal and human glaucoma<sup>93</sup> includes the proteomic identification of oxidatively modified retinal proteins in ocular hypertensive animals.<sup>94</sup> Studies in human glaucoma patients found mitochondrial DNA alterations suggestive of oxidative stress<sup>95</sup> as well as impaired mitochondrial respiratory activity. In addition, lower levels of circulating reduced glutathione were found in the sera of glaucoma patients<sup>96</sup> along with decreased antioxidant enzymes in the aqueous humor of glaucoma patients.<sup>97</sup> Genetic evidence also supports a role for mitochondrial dysfunction, in that some patients with normal pressure glaucoma have been found to express genetic polymorphism of their mitochondrial DNA that bears similarities to those found in patients with Leber's hereditary optic neuropathy and dominant optic atrophy.<sup>98</sup>

## Inflammatory Cytokines

A pathogenic role for inflammatory cytokines such as tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) and nitric oxide have been postulated based on tissue examination of postmortem human glaucomatous eyes.<sup>99–102</sup> Functional studies of cultured RGCs and experimental glaucoma also demonstrated that RGC death could be reduced favorably by treatment with agents that neutralize or halt production of TNF- $\alpha$ <sup>103–105</sup> or nitric oxide synthase,<sup>106</sup> although the role of nitric oxide synthase remains controversial,<sup>107</sup> and nitric oxide donors are currently moving through clinical trials as IOP-lowering agents. The suggestion that TNF is causally implicated in glaucoma was initially supported by the finding that there were mutations in the gene for optineurin, a protein involved in the TNF signaling cascade, in a cohort of glaucoma patients.<sup>108</sup> However, it is not clear if this mutation or if TNF- $\alpha$  polymorphisms are significant factors for all the patient populations in which they have been studied.<sup>109–111</sup> A role for other signaling molecules considered cytokines or members of inflammatory cascades such as complement proteins like C1q<sup>112–114</sup> and interleukins such as IL-6 and IL-1 $\alpha$ <sup>115,116</sup> have also been implicated as causative agents in promoting RGC death or as key to regenerative failure.

## Aberrant Immunity

Both the humoral and cellular immune system have been implicated in glaucomatous neurodegeneration. For the humoral system of immunoglobulins, an increased prevalence of monoclonal gammopathy,<sup>117</sup> retinal immunoglobulin deposition,<sup>118</sup> elevated serum autoantibody titers to optic nerve head glycosaminoglycans<sup>119</sup> or to retinal antigens, including rhodopsin,<sup>120</sup> heat shock proteins,<sup>121,122</sup> gamma-enolase,<sup>123</sup> alpha-fodrin,<sup>124</sup> neurofilament protein, phosphatidylserine,<sup>125</sup> and glutathione S-transferase,<sup>126</sup> have been reported in patients with glaucoma. The majority of these studies demonstrate that most of these elevated antibody titers occur in patients with normal pressure glaucoma, although many patients with elevated IOP appear to have elevated or, in some cases, decreased antibody titers as well.<sup>127</sup> An autoimmune mechanism that elicits glaucomatous neurodegeneration is hypothesized to occur either directly by autoantibodies<sup>128</sup> or indirectly by a “mimicked” autoimmune response to a sensitizing antigen, which in turn results in neuronal injury.<sup>121,129</sup> It is still unclear whether any of the autoantibodies found in glaucoma patients are of pathogenic importance or whether the autoantibody findings are merely epiphenomena that accompany the disease process.

Evidence supporting the involvement of the cellular immune system in glaucoma includes the presence of HLA-DR-positive microglia in the glaucomatous optic nerve head,<sup>130</sup> the induction of HLA-DR expression and antigen-presenting capacity of optic nerve head astrocytes in glaucoma,<sup>131</sup> and alterations in the cellular immune system, such as an increased percentage of CD8<sup>+</sup> T lymphocytes and altered serum levels of soluble IL-2 cytokine receptors in some patients with glaucoma. On the other hand, a protective immunity may be evoked in injured optic nerve to reduce the secondary degeneration of neurons, which can be induced by active or passive immunization with self-antigens.<sup>132–135</sup> Better understanding the regulation of balance between this protective autoimmune response and induction of an autoimmune disease will be critical to

take advantage of the immune system for neuroprotective strategies in glaucoma.

## Cellular Mechanisms of Apoptosis in Glaucoma

Although the physiological conditions that may mediate glaucomatous optic neuropathy are known, the mechanisms that govern cell survival decisions of the RGC confronted by excessive stress have not been completely elucidated. Unlike the cell necrosis that is accompanied by cell swelling, organelle disintegration, and plasma membrane fracture after, for example, acute severe ischemic insult, the glaucomatous process in RGCs is thought to occur by apoptosis—a degenerative process that features cell shrinkage, plasma membrane blebbing, nuclear DNA cleavage by caspase endonucleases, and cytoskeletal degeneration. The initial evidence for apoptosis in glaucoma relied on markers of nuclear DNA cleavage<sup>136,137</sup> but has since been far more extensively studied.<sup>92,93</sup> Mitochondrial-dependent apoptosis involves the induction of proapoptotic proteins such as BAX (and related family members BAK, BI, and BAD) that increase mitochondrial membrane permeability. This subsequently promotes activation of the cell executioner caspase enzymes, which in turn activate DNA breakdown. Normally, BAX activation is balanced intracellularly by activation of a family of BCL-2 (or BCL-XL) proteins that decrease mitochondrial membrane permeability and reduce or prevent apoptosis. The central role of the cellular proteins BAX and BCL-2 lie in stoichiometric balance with one another (Fig. 10.3.4) that ultimately determines whether apoptosis will occur.<sup>92,138,139</sup>

## Neurotrophic Factors for Survival and Growth

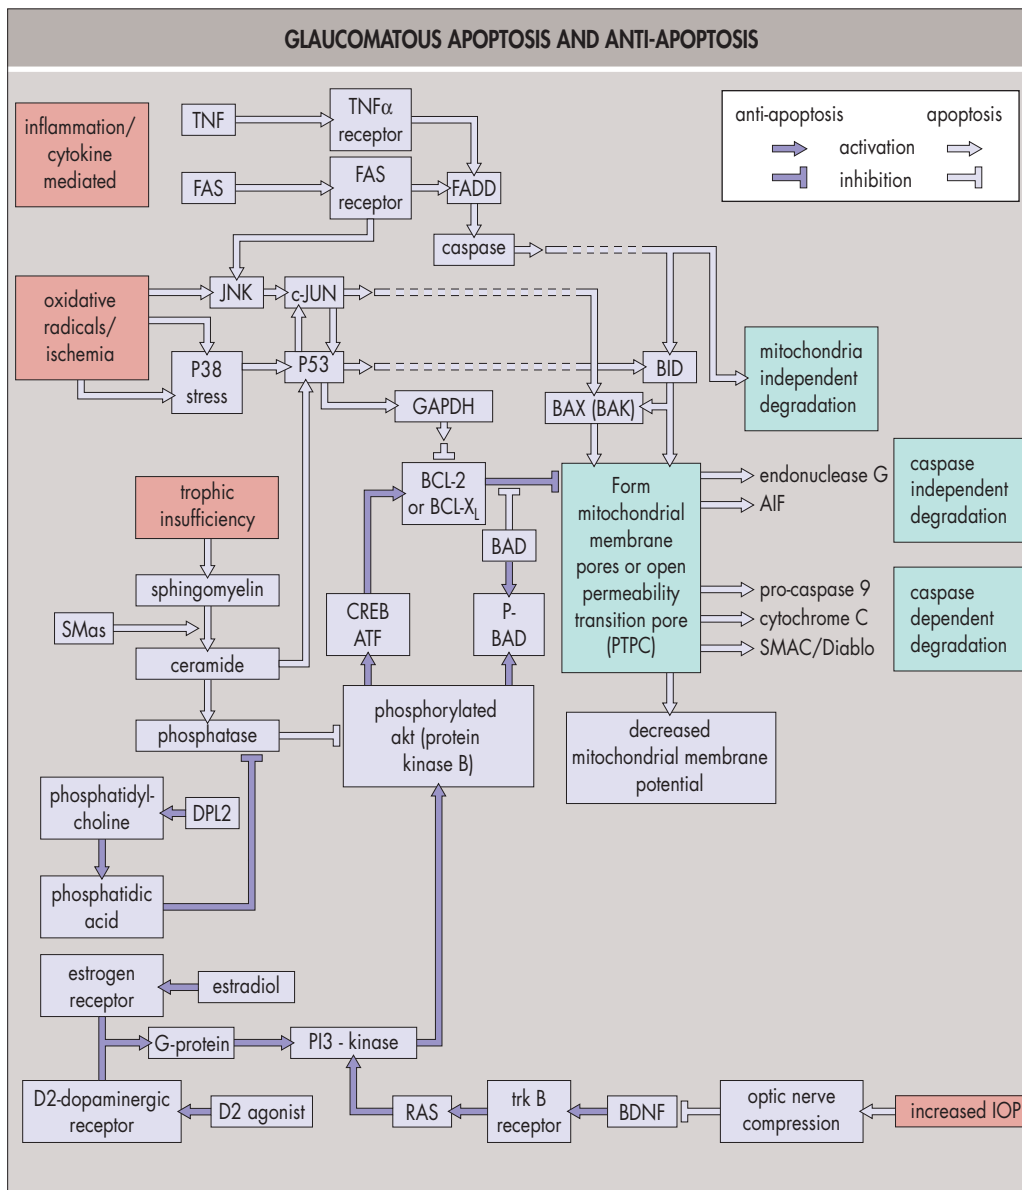

The extracellular signaling from neurotrophic factors and their cellular receptors appear also to have major effects (both helpful and harmful) on RGC cell fate.<sup>92</sup> These proteins are found in the developing and adult visual system and normally support RGC survival and axon growth. As noted above, RGC axon damage at the optic nerve head results in a blockade of the transport of factors such as BDNF and its receptors in acute glaucoma.<sup>79,140,141</sup> In preclinical models, RGC neuroprotection can be elicited by BDNF<sup>142</sup> or other neurotrophic factors, including ciliary neurotrophic factor (CNTF),<sup>143</sup> glial-derived neurotrophic factor (GDNF),<sup>144</sup> and nerve growth factor (NGF).<sup>145,146,147,148</sup> Neurotrophic factors have entered human testing, including trials in glaucoma for CNTF and NGF.

## Central Visual Pathway Degeneration in Glaucoma

Although glaucoma is characterized best as an axonopathy that initiates or propagates at the optic nerve head, it is also characterized by changes in RGCs' axon target fields in their central visual pathways in the brain, such as at the lateral geniculate nucleus (LGN) and even downstream at the visual cortex. Chronic IOP elevation in primates leads to microglial cell and astrocyte activation in the LGN, observed by positron emission tomography imaging and by histology.<sup>149</sup> Neuroimaging of human glaucoma patients suggests differences in LGN volume measurable by magnetic resonance imaging (MRI), and RGC loss in glaucoma patients is associated with transsynaptic death of the neurons in the LGN.<sup>49,50,150,151</sup> Thus glaucomatous neuronal death is not limited to the retina, because neurons in the lateral geniculate and the visual cortex also appear to be lost.<sup>152,153</sup>

## CONCLUSIONS AND FUTURE DIRECTIONS

Glaucoma is no longer viewed simply as elevated IOP that damages the optic nerve. In addition to high IOP, functional evidence is rapidly accumulating that suggests damage to the optic nerve may be initiated or sustained by many factors, including ischemia, excitotoxicity, neurotrophin insufficiency, inflammatory cytokine damage, the immune environment (including aberrant immunity), neuronal–glial interactions, complement regulation of synaptic transmission, and other factors not yet defined. Our understanding of glaucoma more broadly as a neurodegenerative disease broadens the candidate approaches to treatment beyond just lowering IOP to include neuroprotective and regenerative therapies. Such novel therapies may complement current glaucoma therapy and move us toward targeted treatment of neural injury and regeneration throughout the visual system.

**Fig. 10.3.4 Cellular Signaling Mechanisms for Glaucomatous Apoptosis and Anti-Apoptosis.** The schematic is drawn to illustrate the role of BAX and BCL family of proteins in the induction of increased mitochondrial membrane permeability that allows the release of the different factors (endonuclease G, AIF, pro-caspase 9, cytochrome C, and SMAC/Diablo) leading to caspase-dependent or independent apoptotic degradation in retinal ganglion cells in glaucoma in response to several physiological stress conditions thought to be pertinent to the etiology of glaucomatous degeneration. # Clinical Examination of Glaucoma

Daniel Lee, Edward S. Yung, L. Jay Katz

# 10.4

**Definition:** Glaucoma is a group of acute and chronic, progressive, multifactorial optic neuropathies and is diagnosed via history, clinical examination, and ancillary testing in which intraocular pressure and other contributing factors are responsible for a characteristic acquired loss of retinal ganglion cell axons leading to atrophy of the optic nerve with demonstrable visual field defects.

## Key Features

- Obtaining relevant information.
- Assessing the patient's functional status.
- Obtaining the patient's history.
- Examination techniques.
- Visual acuity testing.
- Pupillary response testing.
- Tonometry.
- Pachymetry.
- External examination.
- Slit-lamp examination.
- Gonioscopy.
- Optic nerve examination.
- Testing for glaucoma.

## INTRODUCTION

The clinical evaluation of glaucoma requires thorough review of a patient's medical and ocular history as well as a comprehensive ocular examination that should include visual acuity testing, pupillary response testing, slit-lamp biomicroscopy, tonometry, gonioscopy, and optic nerve examination. In addition to the information obtained during the clinical examination, ancillary diagnostic tests can also help the clinician assess the structural and functional integrity of the optic nerve.

The goal of the clinical evaluation is to diagnose the type of glaucoma affecting the patient, assess its severity, and determine the presence of progression over time. Based on the findings, appropriate individualized therapeutic options may be offered to the patient.

## OBTAINING CLINICALLY RELEVANT INFORMATION

### Assessing the Patient's Functional Status

The first step in the clinical evaluation of glaucoma is determining the functional status of the patient. An indirect way of measuring the functional status consists of estimating the general health and life expectancy of the patient. This assessment can also provide the clinician with important insight regarding the patient's conceptions and attitudes toward their disease. Since glaucoma is a chronic disease, the clinician must gauge the patient's degree of understanding, motivation, and willingness to participate in his or her care.

Assessment of a patient's functional status enables the clinician to individualize and appropriately adjust the intensity and aggressiveness of treatment. Matching the physician's expectations with the patient's understanding of his or her disease is likely to result in better communication, which may lead to better adherence to therapy by the patient.

## Obtaining the Patient's History

### Medical History

It is important to establish a chronology of events leading up to the patient's current condition by documenting the onset, duration, location, severity, and perceived progression of his or her symptoms, if any. Additionally, the clinician must identify drug allergies, the patient's ability to tolerate topical and systemic medications, and the presence of systemic health disorders that could be associated with the patient's type of glaucoma.

Clinicians should pay special attention to a patient's use of corticosteroids, regardless of the duration of use, since these have been associated with elevated intraocular pressures (IOP).<sup>1</sup> Patients with a history of glaucoma or a family history of glaucoma are more prone to IOP increases with corticosteroid use than both glaucoma suspects and normal patients. While an increase in IOP is more likely to occur with topical corticosteroid administration, it may also occur with various systemic routes of administration. Other important systemic drugs to note include sulfonamide drugs such as topiramate and acetazolamide, bupropion, oseltamivir, and antidepressant medications, which have been reported to cause acute myopia with uveal effusions and acute, bilateral, angle-closure glaucoma.<sup>2,3</sup> In addition, drugs like antihistamines and antispasmodics may lead to mydriasis and compromising narrow angles.<sup>1</sup>

### Ocular History

A thorough review of the patient's ocular history should include an assessment of the following factors:

- Refractive status – Hyperopic eyes may be predisposed to developing angle-closure glaucoma. Myopic eyes may be predisposed to developing pigmentary glaucoma<sup>4</sup> or primary open-angle glaucoma<sup>5</sup> (POAG) and may have suspicious discs, which should be differentiated from congenitally tilted discs that remain stationary throughout life.
- Previous intraocular surgery – Refractive surgery such as laser-assisted in situ keratomileusis (LASIK) or photorefractive keratectomy (PRK) may lead to corneal biomechanical changes and thinning, which can affect accurate measurement of IOP (see later). Complications of previous intraocular surgeries may predispose to inflammatory glaucoma.
- History of blunt ocular trauma – Blunt trauma can lead to hyphema, traumatic dysfunction of the trabecular meshwork, angle recession, and glaucoma.
- Ability of the patient to tolerate topical glaucoma medications.

### Family History

A positive family history is a known risk factor of glaucoma.<sup>6</sup> The prevalence of glaucoma, enlarged cup-to-disc ratio (CDR), and increased IOP have been found to be higher in children and siblings of glaucoma patients compared to the relatives of controls.<sup>7</sup> In addition, several genes and different modes of inheritance have been implicated in the development of various forms of glaucoma and will be discussed in greater detail in Chapter 10.34. Therefore, patients should be asked about any relatives who have been diagnosed with glaucoma. Special attention should be paid to the age of diagnosis, presentation, systemic associations, progression, and visual status of the affected relative.

### Ethnicity

The prevalence of glaucoma varies among different ethnic groups. Angle-closure glaucoma is more common among East Asian,<sup>8</sup> Indian,<sup>9</sup> and Inuit<sup>10</sup> populations than among white populations.

POAG is more prevalent, appears earlier, and progresses more rapidly in individuals of African descent compared with individuals of European descent.<sup>11,12</sup> The Los Angeles Latino Eye Study also found that POAG was

more prevalent in Hispanic patients than in non-Hispanic white patients in the United States.<sup>13</sup>

EXAMINATION TECHNIQUES

Visual Acuity Testing

Visual acuity testing is an essential part of the evaluation of the glaucoma patient since it provides information to the clinician about the patient’s functional status.

However, in the early stages of glaucoma, central visual acuity is preserved and may remain intact even until the last stages of the disease. Therefore, visual acuity alone does not always provide sufficient information to evaluate the severity of glaucoma. Nevertheless, in very advanced glaucoma cases, visual acuity can play an important role in the selection of one treatment option over another. Subjective decreases in visual acuity in very advanced cases may also be an indicator of progression when visual field testing is no longer reliable.

Pupillary Response Testing

Testing for a relative afferent pupillary defect (RAPD) is an often overlooked component of the glaucoma evaluation. A positive RAPD is found only in the presence of a definite abnormality of the afferent limb of the pupillary light reflex pathway and may signify the presence of asymmetrical optic nerve damage. It has been suspected that a positive RAPD may present before visual field and optic disc changes become apparent.<sup>14</sup> Two studies<sup>15,16</sup> evaluating the relationship between RAPD and retinal nerve fiber layer (RNFL) thickness suggest that an RAPD will be detectable when there is a greater than 17%–27% reduction in RNFL thickness in the eye with the RAPD relative to the fellow eye.

While pupillometry<sup>14,17,18</sup> has been used for RAPD detection, RAPD testing is still traditionally performed using the swinging flashlight method (SFM).<sup>19</sup> The sensitivity of RAPD detection using the SFM may be increased by using the magnifier-assisted swinging flashlight method in which a +20.00 diopter (D) lens is held in front of the tested eye.<sup>14,20</sup> After an RAPD is detected, it can be quantified with the aid of tools such as neutral density filters,<sup>21</sup> cross-polarized filters,<sup>22</sup> or a Sbisa bar.<sup>23</sup>

Tonometry

The Role of Intraocular Pressure in Glaucoma

The measurement of IOP plays a central role in the examination of the glaucoma patient. While the mean IOP in population studies has been measured to be roughly 15–17 mm Hg,<sup>24</sup> it is important to note that the IOP distribution among the general population does not follow a normal bell-shaped (Gaussian) curve. Instead, the distribution is skewed toward higher pressures. As a result of this skewed distribution, it is incorrect to determine 95% limits using the equation mean  $\pm$ 2.5 standard deviations (SD). In other words, 21 mm Hg (i.e., 2.5 SD above the mean) cannot truly be considered a standard cutoff value to differentiate normal from abnormal IOP. Instead, consideration of a patient’s IOP should be individualized.

IOP is dynamic; IOP monitoring studies have shown that individual IOP exhibits significant long-term, diurnal, positional, and nocturnal fluctuations.<sup>25–32</sup> These studies (1) illustrate the importance of multiple pressure readings in patients being evaluated for glaucoma, and (2) highlight the limitations of office-based tonometry in which only a snapshot of the patient’s pressures is recorded and peak IOP levels are missed in up to 62% of patients.<sup>33,34</sup> Some, though not all, long-term IOP fluctuation studies have also reported an association between IOP fluctuation and disease progression.<sup>26–32</sup> Therefore, it is important for clinicians to consider the possibility that patients may benefit from the assessment and modulation of IOP fluctuations. In select glaucoma patients, IOP fluctuations may also justify the use of diurnal pressure curves and possibly, in the future, continuous/home IOP monitoring.<sup>35</sup>

Factors reported to be associated with IOP elevation and reduction are listed in Table 10.4.1.<sup>1,36–44</sup>

IOP is the only known modifiable factor that has been shown to delay progression of disease in both ocular hypertensive<sup>45</sup> and glaucoma patients.<sup>46–48</sup> Therefore, most recognized therapeutic interventions for glaucoma (medications, laser, and surgery) are directed at lowering IOP.

Clinical measurement of IOP has undergone several technical advances since the era of digital tension measurements and indentation tonometry. While the future of IOP testing now rests with novel techniques of achieving continuous IOP monitoring, the current reference standard and most

TABLE 10.4.1 Factors Associated With Elevation and Reduction of Intraocular Pressure (IOP)

Factors Associated With IOP Elevation	Factors Associated With IOP Reduction
Supine position	Prolonged exercise
Valsalva maneuver	Pregnancy
Elevated episcleral venous pressure	Metabolic acidosis
Sympathomimetics and anticholinergic agents in narrow angles	Intake of alcohol Marijuana
Corticosteroids Ketamine and succinylcholine	General anesthetics (except for ketamine and succinylcholine)

widely used method for the measurement of IOP remains the Goldmann applanation tonometer (GAT). The principles and technique of Goldmann tonometry are described in detail later. Listed in Table 10.4.2 are the mechanisms, advantages, and disadvantages of other tonometry methods<sup>49,50</sup> including Schiøtz indentation tonometry, Tono-Pen, noncontact tonometry, pneumotonometry, rebound tonometry, dynamic contour tonometry, and transpalpebral tonometry.

Applanation Tonometry

GAT is based on the Imbert–Fick principle, which states that the force necessary to applanate a perfectly elastic, infinitely thin, dry sphere divided by the area flattened ( $P = F/A$ ) equals the pressure inside the sphere. In an attempt to account for corneal thickness, scleral rigidity, and the tear film’s surface tension, the area of applanation was set at 7.35 mm<sup>2</sup> (diameter 3.06 mm).

The tonometer’s head is made of plastic; the tip has a built-in transparent biprism, which divides the image seen through the tonometer head into two equal semicircles or mires. The cornea is anesthetized and fluorescein is applied to improve visualization of the two semicircles using a cobalt blue light. The tonometer’s head is gently applied to the surface of the cornea, and a variable force is applied using a sensitive spring system regulated by a dial. The dial is turned in either direction until the inner edges of the mires just meet. This corresponds to the applanating force necessary to flatten an area 3.06 mm in diameter. The force magnitude on the dial is expressed in dynes, and this value is multiplied by 10 to determine the IOP (mm Hg).

IOP measurements with GAT are limited by the presence of corneal astigmatism greater than 3.00 D.<sup>51</sup> This potential error can be avoided by using the average of two measurements taken 90° apart (vertical and horizontal axes at right angles) or by aligning the tonometer biprisms so that the red line on the prism holder is aligned to the corneal axis of negative cylinder or least corneal curvature.<sup>52</sup>

Careful attention must be paid by the examiner to avoid complications associated with GAT, including corneal abrasions and corneal decompensation secondary to topical anesthetic use. The tip of the tonometer should always be wiped with either hydrogen peroxide solution or with a 70% isopropyl alcohol pad to prevent infection<sup>53</sup> and thoroughly dried before use to avoid a chemical burn to the cornea. Special steps should be taken after applanation of patients with hepatitis C virus (HCV) to ensure adequate sterilization. Options include wiping the tonometer tip with povidone iodine 10% for 15 seconds, or soaking the tip in 3% hydrogen peroxide or 70% isopropyl alcohol for 5 minutes.<sup>54</sup> Calibration of this instrument should be performed at least twice a year. A modified version of the Goldmann tonometer, the Perkins and Draeger tonometer, is portable and may be used while the patient is supine.

Pachymetry

Assessment of central corneal thickness (CCT) has become an important element of the clinical evaluation of the glaucoma patient. Ultrasound pachymetry is easy, portable, and the most widely used method of measuring CCT, though several other methods have been employed, including optical pachymetry, optical coherence tomography (OCT), specular microscopy, and Scheimpflug imaging.

A large meta-analysis of 230 data sets found the normal CCT to be 536  $\mu$ m (SD 31  $\mu$ m).<sup>55</sup> Twin studies<sup>56,57</sup> have shown that CCT is a highly heritable trait, and several population studies indicate that CCT varies among different ethnic groups.<sup>58</sup> For example, individuals of African descent have thinner mean CCT values than Hispanic people and non-Hispanic white people in the United States. CCT may also vary between different diagnoses; eyes with normal-tension glaucoma and ocular hypertension may have thinner and thicker CCT values relative to controls, respectively.<sup>59</sup>

TABLE 10.4.2 The Mechanisms, Advantages, and Disadvantages of Different Tonometry Methods

Tonometry Method	Mechanism	Advantages	Disadvantages
Goldmann applanation	See text	Widespread use Considered the reference standard	Overestimation with too much fluorescein, very thick or steep corneas, eyelid squeezing, direct or indirect pressure on the globe, Valsalva maneuvers Underestimation with too little fluorescein, corneal edema, thin corneas Affected by scleral rigidity Cannot be used reliably in corneas with significant irregularities or scarring Affected by operator bias
Schiøtz indentation	The cornea is indented by a metallic footplate attached to a plunger of known (and variable) weight. Movement of a lever along an attached scale indicates pressure. A large displacement of the lever represents low pressure, and small displacement represents high pressure. Conversion table used to obtain IOP in mm Hg.	Portable May be sterilized for OR use	Cannot be used upright (unless head tilted far back) Affected by corneal thickness, irregular/scarred cornea, and scleral rigidity Risk of corneal abrasion if eye moves
Tono-Pen	Mixed indentation and applanation mechanism. A small strain gauge surrounded by an annular applanation surface detects pressure at point of applanation. Applanation point detected by a small decrease in the pressure transmitted through strain gauge (when the applanation surface shares a portion of the force). Pressure is calculated from multiple readings (4 or 10) taken electronically.	Highly portable, easy to use Position-independent Digital readout Can use over bandage contact lens Disposable covers (no need to sanitize) Can be used on corneas with significant scarring or irregularity	Cost of disposable covers and battery In some cases, readings can vary significantly from Goldmann
Non-contact (Airpuff)	Similar to Goldmann, except applanation (diameter 3.06 mm) achieved by a column of air that increases in intensity. A sensor detects applanation  A newer version, the ocular response analyzer, has ability to measure corneal hysteresis by detecting the difference between two applanation pressures, one on initial applanation and the other on applanation following indentation beyond the initial applanation point.	No anesthesia or sterilization required	Most are not portable Frequent maintenance needed Corneal thickness may influence measurement more than Goldmann (except ocular response analyzer)
Pneumotonometry	A slightly convex tip resting on a cushion of air is used to applanate the cornea. A strain gauge detects the pressure. The tip is held for at least 5 seconds and IOP pulsation can be traced.	Portable Position-independent	Expensive parts Frequent maintenance needed Sanitation is difficult
Rebound	A small magnetized, ball-shaped probe is projected forward to bounce off the cornea at the push of a button. The speed of deceleration is used to calculate pressure. More rapid deceleration indicates higher pressure.	Portable Easy to use No anesthesia required Patient comfort Disposable probes	Cost of disposable probes Corneal thickness may influence measurement more than Goldmann
Dynamic contour tonometry (Pascal)	A concave-shaped plastic tip (contour-matched to the cornea) with a central pressure sensor is applied to the cornea at a constant force of 1 g. No applanation or indentation. Pressure is read from outside the cornea, 100 times/sec for several seconds, until an audible signal is heard. Reports IOP (based on average diastolic pressure), ocular pulse amplitude (systolic minus diastolic IOP), and quality of reading.	Digital readout Disposable covers (no need to sanitize) More independent of corneal thickness than Goldmann Accurate in thin eyes and post-LASIK eyes Reports ocular pulse amplitude	Expensive Cost of disposable covers Learning curve
Transpalpebral	Pressure measured mechanically or electronically (depending on device) through the upper eyelid or by digital palpation	Only useful when conventional tonometry not possible—corneal prostheses, extremely irregular or scarred corneas, uncooperative patient Lack of need for anesthesia or sterilization	Readings vary significantly from Goldmann Reading significantly affected by corneal thickness

IOP, Intraocular pressure; LASIK, laser-assisted in situ keratomileusis.

Measurement of CCT is important for two reasons. CCT influences the measurement of IOP in many types of tonometry, including GAT, and CCT may have a prognostic value for patients with ocular hypertension. Although CCT is set as a constant variable in the Goldmann tonometry formula, pachymetry studies have demonstrated that CCT varies significantly between individuals and influences IOP measurement. “True” IOP is underestimated in thin corneas and overestimated in thicker corneas. Therefore, clinicians should consider interpreting borderline or unusual IOPs in light of a patient’s CCT and, in cases of doubt, consider re-evaluating IOP using a tonometry method that is less dependent on CCT. In several studies,<sup>60–62</sup> including the Ocular Hypertension Treatment Study (OHTS)<sup>63</sup> and the European Glaucoma Prevention Study (EGPS),<sup>64</sup> CCT was found to be a powerful and independent predictor of the development of POAG. In OHTS, ocular hypertensive eyes with thin corneas (<555 μm) were found to have a threefold increased risk of developing POAG compared to eyes with thick corneas (>588 μm). It is important to note, however, that OHTS did not adjust IOP values to account for CCT. Measured IOP values in eyes with lower CCT could have been a significant underestimation of their true values compared to measurements from eyes with thicker corneas. Because possible CCT-induced GAT measurement error were not adjusted for, these studies did not truly separate CCT from IOP.

To address this issue, another study<sup>65</sup> re-evaluated the OHTS data and applied five different correction formulas to adjust the IOP values for CCT. In this analysis, CCT remained a statistically significant predictor of glaucoma development in ocular hypertensives, though the hazard ratio decreased from 1.84 to 1.38–1.69 with the different correction formulas. Although this result is not conclusive<sup>66</sup> due to the inherent limitations of correction formulas and requires more investigation, it does suggest the possibility that CCT may be important not only for adjusting IOP assessments but also as an indicator of glaucoma risk. The cause of this potentially increased risk conferred by thinner central corneas remains unknown, though it is possible that CCT is biomechanically related to other anatomical structures implicated in glaucoma pathogenesis, such as the optic disc, lamina cribrosa, and sclera.

### External Examination

The importance of the external examination of the ocular adnexae is emphasized in this section because a variety of systemic conditions have been associated with characteristic external findings and the development of secondary glaucomas (Table 10.4.3).

In addition, external examination of the lids and the ocular surface can provide the clinician with important clues regarding the presence of

TABLE 10.4.3 Ocular Adnexae Abnormalities and Systemic Findings Associated With Secondary Glaucomas

Condition	Periocular Findings	Intraocular Findings	Systemic
<b>Tuberous Sclerosis</b>	Ash-leaf sign (hypopigmented macules) Angiofibromas (yellow–red papules in malar regions of face)	Retinal/optic nerve hamartomas Punched-out chorioretinal depigmentation Iris abnormalities	Benign tumors in various organs Renal abnormalities Seizures Shagreen patches
<b>Neurofibromatosis Type 1</b>	Plexiform neurofibroma (S-shaped upper lid tumor) Pulsating proptosis	Angle abnormalities Lisch nodules Choroid hamartomas Retinal tumors Optic nerve glioma	Café-au-lait spots Axillary/inguinal freckling Distinct bone abnormalities
<b>Juvenile Xanthogranuloma</b>	Reddish or yellow–brown papules, plaques, or nodules on eyelid	Iris heterochromia Iris masses Spontaneous hyphema	Reddish or yellow–brown papules, plaques, or nodules on head/neck/trunk Subcutaneous or deep soft tissue nodule/mass Systemic lesions in various organs
<b>Ocular or Oculodermal Melanocytosis (Nevus of Ota)</b>	Gray–brown to blue–black lesion in distribution of first and second cranial nerves involving episclera or periocular skin	Pigmentary-like glaucoma	Increased incidence of melanoma involving uvea, central nervous system, orbit, skin
<b>Axenfeld–Rieger Syndrome</b>	Hypertelorism (increased distance between the two orbits)	Posterior embryotoxon Abnormal angle tissue Iris abnormalities (corectopia, polycoria)	Maxillary and dental hypoplasia Microdontia, hypodontia, anodontia Pituitary abnormalities Hypospadias (males) Umbilical abnormalities
<b>Orbital Varices</b>	Variable or intermittent unilateral proptosis, engorgement, and pain	Elevated episcleral venous pressure	
<b>Thyroid Ophthalmopathy</b>	Exophthalmos Lid retraction	Motility restriction Conjunctival chemosis Elevated episcleral venous pressure	Hyperthyroid Hypothyroid Euthyroid
<b>Sturge–Weber Syndrome</b>	Facial capillary malformation (port wine stain)	Vascular malformations of conjunctiva, episclera, choroid, retina Iris heterochromia Elevated episcleral venous pressure	Intracranial capillary–venous malformations
<b>Superior Vena Cava Syndrome</b>	Proptosis Facial edema Eyelid edema	Conjunctival chemosis Elevated episcleral venous pressure	Lung cancer or non-Hodgkin's lymphoma Dyspnea Venous distension in neck and chest Extremity swelling

medication-related toxicity. Ocular and systemic side effects associated with the use of glaucoma medications are listed in Table 10.4.4. Systemic side effects from topical glaucoma therapy can be minimized by performing punctal occlusion, blotting of excess drops, and possibly closing the eyelids after instillation.<sup>67</sup>

Allergic contact dermatitis is manifested with thickening of the skin overlying the lids. Alpha-2 agonists (brimonidine) have been implicated with this condition along with other older medications such as epinephrine, apraclonidine, and pilocarpine. This allergic contact dermatitis can progress and lead to scarring and obstruction of the lacrimal punctae.<sup>68</sup>

Topical administration of prostaglandin analogs has been associated with hypertrichosis, hyperpigmentation of the eyelashes and periocular area, irreversible iris darkening,<sup>69</sup> and deepening of the upper eyelid sulcus, possibly caused by periorbital fat atrophy.<sup>70</sup>

Topical glaucoma medications can be toxic to the ocular surface and can worsen the signs and symptoms of dry eye. This can make susceptible patients intolerant to some preparations and may limit their choices of topical glaucoma therapy. A methodical investigation of the ocular surface and the identification of dry eye and blepharitis can help the clinician address the underlying cause before the institution or adjustment of glaucoma treatment.

## Slit-lamp Examination

### Conjunctiva, Sclera, and Episclera

The conjunctiva plays an important role in the evaluation of glaucoma patients because the success of glaucoma surgery depends on the health and integrity of this tissue. Improving the health of the ocular surface can result in better surgical outcomes in glaucoma.

The clinician must evaluate the presence of conjunctival hyperemia and determine the etiology of this finding to treat the underlying cause. There are three major causes of conjunctival hyperemia that need to be recognized: (1) medication or preservative-induced hyperemia; (2) dilated episcleral vessels; and (3) infectious causes when a filtering bleb is present.

The presence of conjunctival hyperemia, conjunctival follicles, and superficial punctate keratitis should be assessed when patients are using IOP-lowering eyedrops. A significant number of patients using topical

glaucoma medications suffer from ocular surface disease (OSD).<sup>71</sup> Furthermore, OSD incidence and symptom severity is positively correlated with the number of eyedrops administered.<sup>71</sup> Much of the OSD caused by glaucoma medications is likely attributable to added preservatives. Although preservatives function to prevent bacterial contamination and improve ocular penetration, patients using preserved eyedrops have a significantly increased incidence of OSD signs and symptoms such as discomfort upon instillation, burning or stinging, foreign body sensation, and dry eye sensation.<sup>72</sup> The most common preservative employed in glaucoma medications is benzalkonium chloride (BAK). Recently, milder proprietary preservatives such as SofZia (Travatan Z; Alcon Laboratories, Inc.) and Purite (Alphagan P; Allergan, Inc.) have been introduced. Several glaucoma drops are also available in preservative-free formulations, such as timolol, tafluprost, and fixed-combination timolol-dorzolamide.

The presence of dilated episcleral vessels should prompt the physician to investigate the presence of elevated episcleral venous pressure, which can reduce aqueous outflow and lead to an elevation of IOP.<sup>73</sup> Patients with elevated episcleral venous pressure often have blood in Schlemm's canal that is visible on gonioscopy.<sup>73,74</sup> Etiologies of elevated episcleral venous pressure include: (1) carotid cavernous sinus fistula<sup>74</sup>; (2) Sturge–Weber syndrome,<sup>73</sup> which is associated with a facial port wine stain; (3) the systemic form of Klippel–Trenaumay–Weber syndrome,<sup>75</sup> which is associated with ipsilateral limb hypertrophy and cutaneous hemangiomas; (4) thyroid ophthalmopathy; and (5) superior vena cava syndrome. A single dilated episcleral vessel should prompt an investigation for an occult ciliary body melanoma,<sup>76</sup> which should include a dilated exam and diagnostic ultrasound biomicroscopy.

The presence of a filtering bleb should be noted in the patient's chart, with careful documentation of the bleb's height, extent, vascularity, and integrity (Seidel test).<sup>77</sup>

### Cornea

Examination of the cornea should be performed carefully to establish the presence of infiltrates, edema, staining, or abnormalities associated with the development of secondary glaucomas. Eyes with a history of penetrating keratoplasty have a high incidence of developing secondary glaucoma, with initial elevations in IOP occurring an average of 6 months after surgery.<sup>78</sup>

^Many of these medications may cause conjunctival hyperemia, conjunctivitis, blurred vision, eye discomfort, foreign body sensation, dry eye, or allergic reactions; therefore these side effects are not included in the table. BAK, Benzalkonium chloride; CNS, central nervous system.			

Relevant epithelial abnormalities in glaucoma patients include inferior staining associated with medicamentosa reactions, microcystic edema associated with acutely elevated IOP, and the presence of map-dot-finger-print dystrophy, which can be associated with recurrent corneal erosions. The presence of dendrites on the cornea associated with endotheliitis,

elevated IOP, anterior chamber cell and flare, and keratic precipitates should prompt the clinician to think about a possible trabeculitis caused by a herpes simplex virus infection.<sup>79</sup> The presence of circumferential breaks in Descemet's membrane, also called Haab's striae, indicates the presence of glaucoma of infancy. A

distinction should be made between the horizontally oriented Haab's striae and vertically oriented breaks in Descemet's membrane that occur with forceps-related injuries at birth.<sup>80</sup> Haab's striae should also be differentiated from the endothelial bands seen with posterior polymorphous dystrophy representing epithelialization of endothelial cells, which can invade the anterior chamber angle.<sup>81</sup>

Examination of the corneal endothelium can provide important clues regarding secondary forms of glaucoma. The presence of pigment deposition in a spindle configuration over the inferior portion of the endothelium (also called Krukenberg spindle), iris transillumination defects, and deposition of pigment in the lens capsule have been associated with the pigment dispersion syndrome, which in some cases can lead to IOP elevation and development of pigmentary glaucoma.<sup>4</sup> The presence of corneal guttae and endothelial cells should also be noted, especially when one is considering a combined cataract and glaucoma operation in patients with Fuchs' dystrophy.

A beaten bronze appearance to the corneal endothelium with associated corneal guttae and edema, associated iris abnormalities, and elevated IOP should prompt the diagnosis of the Chandler variant of iridocorneal endothelial (ICE) syndrome, which predominantly presents in young female patients with unilateral glaucomas.<sup>82</sup>

The presence of a prominent and anteriorly displaced Schwalbe's line (also called posterior embryotoxon) along with the presence of high peripheral iris–cornea touch, elevated IOP, and associated systemic findings suggests the diagnosis of Axenfeld–Rieger syndrome.<sup>83</sup> It is important to note that posterior embryotoxon can be found in up to 15% of normal eyes.<sup>84</sup>

Anterior Chamber

Examination of the anterior chamber should include an assessment of the anterior chamber depth using the van Herick method<sup>85</sup> (Table 10.4.5), which will be described in more detail later.

The presence of cell and flare should be determined to establish whether IOP elevation is caused by mechanical obstruction of the trabecular meshwork by inflammatory cells, red blood cells, or macrophages (filled with inflammatory debris, pigment, lens material, or protein), because the management of these conditions may differ significantly.<sup>86</sup>

Iris

The pupil shape should be inspected carefully to identify the presence of corectopia, posterior synechiae, ectropion uvea, or irregularities from previous trauma or acute angle-closure attacks. Unilateral corectopia with patchy, irregular iris atrophy associated with elevated IOP should warrant evaluation for essential iris atrophy variant of ICE syndrome.<sup>87</sup> Bilateral cases would suggest congenital Axenfeld–Rieger syndrome.

Assessment of the curvature of the iris and its anatomical relationship to the cornea may help to identify iris bombé. The surface of the iris must also be inspected for the presence of nodules, masses, and inflammatory membranes. Examining the iris using the red reflex as a background source of illumination can also help the clinician determine the presence of iris transillumination defects, such as those seen with the pigment dispersion syndrome,<sup>4</sup> aniridia, sector atrophy with herpes zoster, and the presence of peripheral iridotomies.

Changes in iris color (heterochromia) should prompt the clinician to look for additional signs associated with Fuchs' heterochromic iridocyclitis, which include diffuse white stellate keratic precipitates, iris atrophy, cells in the anterior chamber, and lens opacities.<sup>88</sup> The presence of associated iris surface matting, nodules, stromal atrophy, and corneal edema is suggestive of Cogan–Reese syndrome.<sup>87</sup> Prostaglandin-induced iris heterochromia can also be present and is irreversible, occurs more frequently in two-tone irides (especially hazel), and is thought to be caused by increased melanogenesis.<sup>89</sup>

Patients with pseudoexfoliation syndrome can present with pupillary ruff defects, iris sphincter transillumination, a characteristic whorl-like

pattern of particulate pigment deposition on the iris sphincter, particulate pigment deposition on the peripheral iris and trabecular meshwork, and exfoliation material on the zonules and ciliary body.<sup>90</sup>

Iris neovascularization in its earlier stages usually presents as vascular tufts at the pupillary margin, which can be easily overlooked if high magnification is not used. Its presence strongly warrants examination of the angle for neovascularization. Although neovascularization of the iris typically precedes the angle, up to 10% of patients with central retinal vein occlusions can develop angle neovascularization without the presence of iris vessels.<sup>91</sup>

Lens

Lens examination is performed through a dilated pupil in order to determine the size, clarity, and stability of the lens (phacodonesis). The anterior surface of the lens should be inspected for the presence of glaukomflecken, which are white subcapsular lens opacities seen after an acute angle-closure glaucoma attack. The presence of pseudoexfoliation material<sup>90</sup> should also be apparent to the examiner once the pupil is dilated. In such cases, the integrity of the zonular apparatus and the amount of pupillary dilation should be noted when considering cataract extraction.

In patients with a history of trauma, examination may reveal instability of the lens (phacodonesis, subluxation, dislocation) or the presence of an annular pigment ring (Vossius ring) on the anterior lens capsule.<sup>92</sup>

The presence of a Scheie line, which consists of pigment deposition on the posterior lens capsule behind the lens equator, is usually associated with the pigment dispersion syndrome.

Pseudophakic glaucoma patients should be carefully examined to determine the type of lens implant present, position of the lens, and integrity of the capsular bag and posterior capsule to rule out the presence of iris chafing syndrome.<sup>93</sup>

Gonioscopy

Estimation of the Peripheral Anterior Chamber Angle

The depth of the peripheral anterior chamber can be assessed at the slit lamp using the van Herick method.<sup>85</sup> A narrow slit beam of light is shone at an angle of 60° in a plane perpendicular to the peripheral cornea. The depth of the space between the corneal endothelium and the peripheral iris is estimated in terms of the thickness of the cornea. This method only provides information about the depth of the anterior chamber angle and in no way replaces the information derived from the direct or indirect visualization of the angle using a goniolens. Grading of the anterior chamber angle according to the van Herick method is described in Table 10.4.5.

Principles of Gonioscopy

Gonioscopy is the technique used to examine the anterior chamber angle or iridocorneal angle. The anterior chamber angle is defined as the angle formed between the anterior surface of the iris and the posterior surface of the cornea and comprises the following anatomical landmarks: Schwalbe's line, anterior and posterior trabecular meshwork, scleral spur, and ciliary body band (Fig. 10.4.1). This angle cannot be visualized directly; the light

Fig. 10.4.1 The Normal Anterior Chamber Angle. This is viewed through the Zeiss lens. Notice the ciliary body band, scleral spur, and trabecular meshwork.

TABLE 10.4.5 Van Herick Grading System

Grade	Depth of Peripheral Anterior Chamber in Terms of Peripheral Corneal Thickness (PCT)
4	≥1 PCT
3	= ¼ to ½ PCT
2	= ¼ PCT
1	≤¼ PCT
0	Narrowed to a slit or no angle

emanating from the anterior chamber angle has an angle of incidence that exceeds the critical angle of the tear–air interface and thus undergoes total internal reflection back into the eye. In gonioscopy, a direct or indirect goniolens is used to overcome total internal reflection and visualize the iridocorneal angle.

Direct Gonioscopy

Direct gonioscopy is performed with a Koepple lens, a dome-shaped, 50.00 D lens that requires an optical coupling solution. The lens is placed over the cornea while the patient is in the supine position, and a direct (i.e., nonreflected) view of the angle is obtained. Although direct gonioscopy may be performed in the office setting using a Barkan microscope in one hand and a light source in the other, its use is now generally reserved for the operating room, using an operating microscope to examine children and perform certain surgical procedures.

Indirect Gonioscopy

Indirect gonioscopy involves the use of goniolenses with built-in mirrors to facilitate visualization of the iridocorneal angle. These mirrors reflect light originating from the opposite section of the anterior chamber angle. Indirect goniolenses include the Zeiss lens (see Fig. 10.4.1) and the Goldmann lens (Fig. 10.4.2).

The Goldmann lens typically has three built-in mirrors, each providing different levels of magnification. The lens requires a viscous coupling solution and is placed against the anesthetized cornea. Lens placement is facilitated by asking the patient to look upward and gently inserting the inferior rim of the lens into the lower fornix. After the lens is in place, the patient is instructed to look forward. With the room lights dimmed and the slit-lamp beam narrowed and shortened (to avoid light entering the pupil), the mirror of the goniolens is illuminated. Visualization of the angle may be optimized by asking the patient to look in the direction of the mirror being examined or gently tilting the lens. The lens is rotated to examine the remaining clock hours of the angle.

The Zeiss lens is a four-mirror lens and is distinguished from the Goldmann lens in three important ways: (1) it does not require a coupling solution; (2) its four mirrors allow visualization of four angle quadrants without rotation of the lens; and (3) it can be used to perform indentation gonioscopy. The initial steps are similar to Goldmann gonioscopy. The lens is placed gently on the center of the cornea, and each angle quadrant is visualized by illuminating the opposite mirror. In the same fashion as the Goldmann lens, asking the patient to look in the direction of the mirror or tilting the lens can enhance the examiner’s view of the angle. The Zeiss lens has a contact surface that is smaller than the diameter of the cornea. This allows for dynamic compression of the cornea, a technique known as indentation gonioscopy. Applying pressure to the cornea will result in displacement of aqueous humor within the anterior chamber and posterior displacement of the peripheral iris, widening of the anterior chamber angle. Indentation gonioscopy allows the clinician to differentiate between appositional closure and synechial closure of the anterior chamber angle; in the latter, indentation will not lead to widening of the angle.<sup>94</sup>

The Zeiss lens may be mounted on a holding fork. Modified Zeiss lenses include the handheld Sussman lens, which is held between the fingers, and the Posner lens, which uses a handle.

Fig. 10.4.2 The Goldmann Lens.

Gonioscopic Grading Systems  
Gonioscopic Anatomy of the Angle

The anatomical landmarks of the anterior chamber angle help orient the examiner and provide important clues for proper grading and description of the angle. When performing gonioscopy, the examiner should identify these landmarks, estimate the angle between the peripheral iris and the cornea, evaluate the insertion and contour of the iris, and note the degree of posterior trabecular meshwork pigmentation.

Several gonioscopic grading systems have been described, among which the two most common are the Shaffer and Spaeth systems.

Shaffer System

The Shaffer system describes the gonioscopic findings in terms of the angular width of the anterior chamber and has a grading system ranging from closed (grade 0) to wide open (grade 4). The angle width is defined by two lines, one extending anteriorly from the point of iris insertion to Schwalbe’s line and the other extending across the surface of the iris from the point of iris insertion.<sup>95</sup> Table 10.4.6 summarizes this system.

Spaeth System

The Spaeth system<sup>96</sup> provides a more complete description of the anterior chamber angle, which includes: (1) the level of iris insertion; (2) the geometric angle formed by the intersection of a line tangential to the trabecular meshwork with a line tangential to the surface of the iris (measured at the point of Schwalbe’s line); (3) the peripheral iris contour; and (4) the degree of pigmentation of the posterior trabecular meshwork (Table 10.4.7). Typically, separate grading of each quadrant is performed.

In addition, the Spaeth classification also uses the dynamic information obtained from indentation gonioscopy, allowing the examiner to differentiate between appositional and synechial closure of the angle (Fig. 10.4.3). The examiner describes the apparent iris insertion as it is first seen and then uses indentation gonioscopy to determine the actual insertion of the iris.

Occludable Angles

Defining an occludable angle is difficult and no standard interpretation exists. Any evidence of peripheral anterior synechiae formation in the setting of gonioscopic narrow angles is suggestive of the development of angle-closure glaucoma and warrants a laser peripheral iridectomy. Based on the Spaeth classification, an eye with an iris insertion of either A or B

TABLE 10.4.6 The Shaffer Angle Grading System

Grade	Angle Width	Description	Risk of Closure
4	35°–45°	Wide open	Impossible
3	20°–35°	Wide open	Impossible
2	10°–20°	Narrow	Possible
1	≤10°	Extremely narrow	Probable
0	0°	Closed	Closed

TABLE 10.4.7 The Spaeth Angle Grading System

Insertion of the Iris
A: Anterior to Schwalbe’s line
B: Between Schwalbe’s line and posterior edge of trabecular meshwork
C: Scleral spur visible
D: Deep, ciliary body visible
E: Extremely deep, >1 mm of ciliary body visible
The <i>apparent</i> insertion ( <b>prior</b> to indentation) is written as (A), (B), or (C)
The <i>true</i> insertion is written without parentheses, e.g., A, B, C, D, E
Iris Angularity (in Degrees)
Possible grades: 0, 5, 10, 15, 20, 25, 30, 35, 40, 45, 50
Iris Curvature
f: flat
b: bowed anteriorly
p: plateau configuration
c: concave posterior bowing
Pigmentation of the Posterior Pigmented Trabecular Meshwork
Pigmentation is graded as 0 (no pigmentation), 1+ (just visible), 2+ (mild), 3+ (marked), or 4+ (intense)
An example of an angle classified by the Spaeth system is (B)C40f 2+. This means that without indentation, the iris insertion is seen anterior to the scleral spur, but after indentation, the scleral spur is visible. The angular width is 40°; the iris has a flat shape; and there is mild pigmentation of the trabecular meshwork.

PORTION OF ANGLE WITH A SYNECHIA AND AREA OF APPOSITIONAL CLOSURE

**Fig. 10.4.3** Portion of Angle With a Synechia and Area of Appositional Closure. Angle view with and without indentation gonioscopy.

**Fig. 10.4.4** Broad Peripheral Anterior Synechiae With Angle Closure.

or an angle of  $10^{\circ}$ – $20^{\circ}$  with a very bowed contour may benefit from a laser iridectomy.<sup>97</sup> Other definitions of an occludable angle include angles with a width of  $20^{\circ}$  or less (Shaffer  $\leq 2$ ) or angles where the posterior trabecular meshwork is visible in less than  $90^{\circ}$  of the angle circumference.<sup>98</sup>

### Specific Findings of the Anterior Chamber Angle

Common gonioscopic findings such as nonuniform iris insertion, peripheral anterior synechiae (Fig. 10.4.4), angle recession (Fig. 10.4.5), cyclodialysis cleft, increased pigmentation of the angle (Fig. 10.4.6), Sampaoles's line, blood vessels in the angle (Fig. 10.4.7), and blood in Schlemm's canal are listed with possible associations in Table 10.4.8.

## Optic Nerve Examination

The examination of the optic nerve probably represents the most important element of the clinical evaluation of the glaucoma patient because structural changes in the optic disc can precede detectable visual field loss in glaucoma.<sup>99</sup> The optic nerve is usually described using the cup-to-disc ratio (CDR) introduced by Armaly in 1967.<sup>100</sup> The CDR is based on the results of three population studies that concluded that the CDR is genetically inherited, symmetric between the two eyes, and not influenced by age.<sup>100</sup> Measurements of the CDR have been shown to have large interobserver variations, likely attributable to differences in definitions and examination methods.<sup>101</sup>

Using CDR alone is not sufficient and has the following limitations:

- It focuses only on the cup size.
- Disc size is not taken into consideration.

**Fig. 10.4.5** Angle Recession (arrows).

DARKLY PIGMENTED TRABECULAR MESHWORK

**Fig. 10.4.6** Darkly Pigmented Trabecular Meshwork.

**Fig. 10.4.7** Neovascularization of an Angle (arrows).

- Focal changes occurring in the neuroretinal rim are not described.
- A disc with a “normal” CDR may have focal thinning or notching.

The size of the optic disc must always be considered when evaluating a patient for glaucoma. Large discs are known to have larger cups and narrower neuroretinal rims without being considered pathological; in contrast, small discs with large cups are usually pathological.

Assessment of the neuroretinal rim has a high diagnostic value in differentiating between normal and glaucomatous discs.<sup>102</sup> An optic nerve head with a normal CDR may have an eccentric cup with a localized neuroretinal rim notch. There is a close relationship between the morphology of the neuroretinal rim and corresponding visual field defects.<sup>103</sup> The neuroretinal rim is defined as the tissue between the disc margin and outer

TABLE 10.4.8 Common Gonioscopic Findings

Common Gonioscopic Findings	Possible Associations
Nonuniform iris insertion	PAS, iris cyst, ciliary body cyst, abnormalities in lens position
PAS (adhesions between the peripheral iris and angle wall)	Distinguish from nonpathological iris processes that are fine, not broad, and do not extend into trabecular meshwork Angle-closure glaucoma, uveitis, neovascularization of the angle, ICE, Axenfeld–Rieger syndrome
Angle recession (posterior displacement of the iris root due to separation of the circular and longitudinal fibers of the ciliary muscle)	Blunt trauma May result in increased intraocular pressure and secondary glaucoma
Cyclodialysis cleft (disinsertion of ciliary body from scleral spur)	Blunt trauma, surgical complication May lead to hypotony
Increased pigmentation of the angle	Pigment dispersion syndrome, pseudoexfoliation syndrome, iris melanoma, trauma, pseudophakic iris chafing syndrome
Sampaolesi’s line (pigment deposition just anterior to Schwalbe’s line)	Pseudoexfoliation syndrome
Blood vessels in the angle	Normal blood vessels are radially oriented, do not arborize, and do not cross the scleral spur Pathological blood vessels are fine, arborizing, and invade the iris surface and extend over the trabecular meshwork to Schwalbe’s line in a nonspecific pattern (see Fig. 10.4.7) Ischemia, e.g. ocular ischemic syndrome, retinal vein occlusion Fuchs’ heterochromatic iridocyclitis
Blood in Schlemm’s canal	Episcleral venous pressure (normal 8–10 mm Hg) that exceeds intraocular pressure Carotid-cavernous fistula, Sturge–Weber syndrome, thyroid ophthalmopathy, superior vena cava syndrome, orbital varices, ocular hypotony

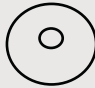

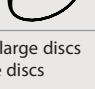

ICE, Iridocorneal endothelial syndrome; PAS, peripheral anterior synechiae.

limits of the optic cup. The “ISNT rule” (which states that, in a normal eye, the neuroretinal rim width follows a characteristic pattern of Inferior ≥ Superior ≥ Nasal ≥ Temporal) may be helpful as a general principle to differentiate normal from glaucomatous nerves, but clinicians should remember that there are many exceptions that do not follow this pattern. Further, closely observing the curvature of blood vessels can aid in identifying the inner edge of the neuroretinal rim.

Based on the limitations of the CDR, several other disc-grading systems have been developed. Among them, the disc damage likelihood scale (DDLS)<sup>104</sup> developed by Spaeth arguably offers the most complete assessment of the optic nerve. The DDLS stages glaucomatous optic nerve damage based on the narrowest width of the neuroretinal rim or, if no rim is present, the circumferential extent of rim absence. This grading system also takes into account the size of the optic disc. The DDLS uses a scoring system ranging from 1 to 10, where 1 is a disc with a low likelihood of glaucomatous damage and 10 represents a severely damaged disc (Table 10.4.9).

The DDLS has several advantages.<sup>104</sup> It has been shown to (1) have a higher intra- and interobserver reproducibility than the CDR system; (2) strongly correlate with visual field changes in patients with glaucoma; and (3) have the best predictive ability to identify glaucomatous damage in comparison with the CDR system and structural imaging with Heidelberg retina tomography (HRT).<sup>105</sup> In addition, the DDLS score can be plotted against the patient’s age and can be used as a means of following the

TABLE 10.4.9 The Disc Damage Likelihood Scale (DDLS)

	DDLS Stage	Narrowest Rim Width (rim/disc ratio) (Average Disc Size: 1.50–2.00 mm)	Example
At risk	1	0.4 or more	
	2	0.3 to 0.39	
	3	0.2 to 0.29	
	4	0.1 to 0.19	
Glaucoma damage	5	less than 0.1	
	6	0 (extension: less than 45°)	
	7	0 (extension: 46°–90°)	
Glaucoma disability	8	0 (extension: 91°–180°)	
	9	0 (extension: 181°–270°)	
	10	0 (extension: more than 270°)	

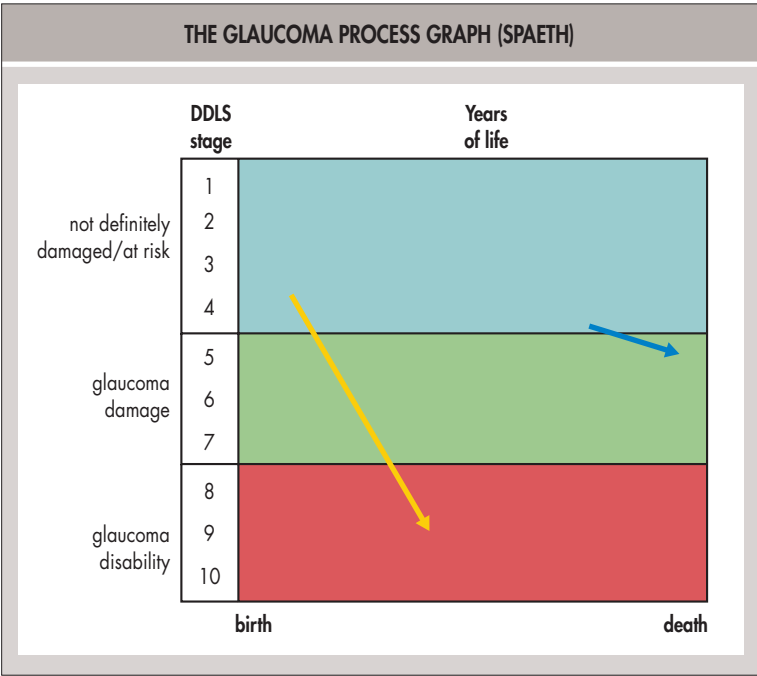

For small discs (diameter <1.5 mm) the DDLS stage should be increased by 1, for large discs (diameter >2.0 mm) the DDLS stage should be decreased by 1, and for very large discs (diameter >3.0 mm), the DDLS stage should be decreased by 2.

rate of change of the optic nerve and progression of glaucoma over time (Fig. 10.4.8).

Lastly, the clinician should also assess for the presence of other key qualitative optic nerve findings including wedge-shaped RNFL defects, splinter or flame-shaped disc hemorrhages, acquired pit of the optic nerve, visibility of the pores of the lamina cribrosa, nasal shift of the central retinal vessels, peripapillary atrophy, and optic disc pallor.

TESTING FOR GLAUCOMA

Several ancillary diagnostic methods can assist the physician by complementing the clinical evaluation of the glaucoma patient. These technologies include ultrasound biomicroscopy, automated perimetry, scanning laser ophthalmoscopy, and optical coherence tomography, among others. These technologies are presented at length in other chapters of this book and will not be discussed here.

**Fig. 10.4.8 The Spaeth Colored Glaucoma Graph.** By plotting the patient’s disc damage likelihood scale (DDLS) stage on this graph, the clinician can monitor progression of disc damage. When combined with estimates of life expectancy, extrapolations of the progression curve can assist the clinician in formulating individualized treatment strategies. The yellow line represents the expected disease trajectory of an individual with early onset, rapidly progressing glaucoma, and the blue line represents the expected disease trajectory of an individual with late onset, slowly progressing glaucoma. The clinician should constantly reassess a patient’s expected disease trajectory at every visit and plan treatment accordingly. In the above figure, the yellow line shows a much steeper and earlier descent into disability compared to the blue line, and therefore warrants a markedly different treatment regimen.

# Visual Field Testing in Glaucoma

Donald L. Budenz, John T. Lind

# 10.5

**Definition:** A diagnostic test critical to the diagnosis and management of glaucoma that measures visual function by assessing sensitivity to light at various points in the field of vision.

## Key Features

- A stimulus of specific size and intensity projected onto a background of standard luminance.
- The threshold light intensity eliciting response to the stimulus is measured at points throughout the field of vision via patient response.

## Associated Features

- Standard automated perimetry uses white light on a white or gray background.
- Short wavelength automated perimetry uses blue light on a yellow background.
- Frequency-doubling technology.
- Testing algorithms—SITA, TOP.
- Software to compare patient to the healthy population (normative database) and measure magnitude and location of any deviation from normal.
- Software to compare multiple tests to assess progression over time.

## INTRODUCTION

Testing of the visual field is the primary method of assessing visual function in glaucoma patients and glaucoma suspects. Because central visual function is most commonly lost late in glaucoma, central visual acuity is a poor test of visual function in glaucoma. Visual field testing is used in three distinct ways in glaucoma evaluation and management: diagnosis, assessment of severity, and determination of progression.

Automated static perimetry using a white stimulus projected onto a white background—also called standard automated perimetry (SAP)—has become the most commonly performed visual field test in glaucoma for a variety of reasons. First, it is more sensitive to early defects than manual kinetic perimetry. Second, since it is computerized, there is less variation in the way the test is performed from operator to operator. Third, statistical programs can be used to do important tasks such as comparing the patients' responses to a normal group of subject responses, subtract out the effect of diffuse depression on the field as occurs in cataract, and provide information on progression. While manual kinetic perimetry is still performed in rare cases, most offices no longer have the equipment or personnel trained in this technique. Instances where manual kinetic perimetry can be useful includes patient with a history of unreliable SAP testing, patients that need to be coached through the test (children of young ages or the elderly), or patients who have difficulty with the standard testing apparatus. And although newer automated techniques such as short wavelength automated perimetry (SWAP) and frequency-doubling technology (FDT) may provide supplemental information in very early cases (both) or in community screening programs, SAP remains the gold standard for assessing visual function in the clinical practice of glaucoma.

## STANDARD AUTOMATED PERIMETRY

### Testing Algorithms in Standard Automated Perimetry

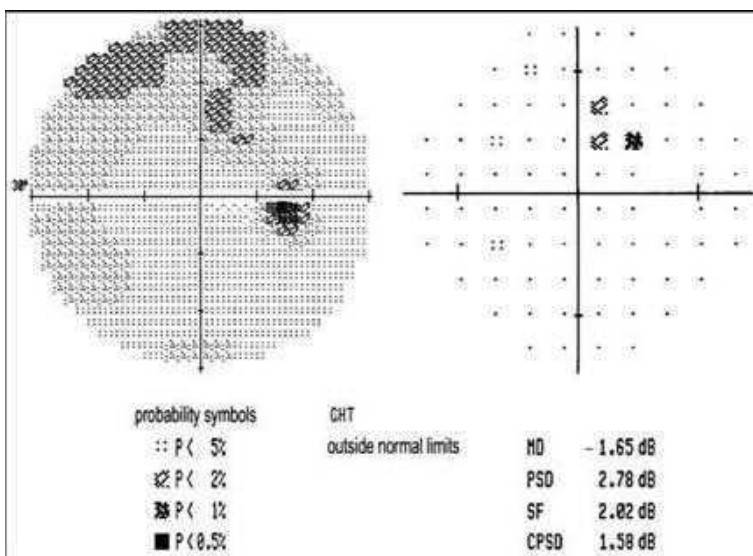

There are a number of different ways to test the visual system's sensitivity to light. Suprathreshold tests present a stimulus brighter than usually seen at a particular location by a normal subject of a particular age and determine whether the subject being tested can see it or not. The actual sensitivity to light is not determined. Suprathreshold testing may be appropriate in a community screening setting or when assessing neuro-ophthalmic, retinal disease, or visual disability (the binocular Esterman field) but is not recommended for glaucoma diagnosis or follow-up. Full-threshold testing is a trial-and-error system whereby stimuli are shown and then increased or decreased in intensity until an estimate is made of the amount of light that can be seen approximately 50% of the time. Full-threshold testing requires greater testing time, and this can result in fatigue effect and false-positive testing. To shorten the test and improve efficiency, the Swedish Interactive Threshold Algorithm (SITA) was developed for the Humphrey Field Analyzer (Carl Zeiss Meditec, Dublin, CA, USA) and the tendency-oriented perimetry (TOP) strategy for the Octopus perimeter (Haag Streit, Berne, Switzerland). There are two SITA programs to choose from: SITA Standard and SITA Fast. With respect to the diagnosis and follow-up of glaucoma, the SITA Standard algorithm is preferred because it appears to give the right balance between sensitivity and specificity while reducing test-taking time by approximately 50% in normal and glaucoma subjects.<sup>1</sup> There is some evidence, however, that the SITA Fast algorithm is more reproducible, which may make it better for following established glaucoma.<sup>2</sup> From a practical standpoint, it is important to stay with the same perimeter and program to follow established glaucoma patients because comparisons between visual field tests performed with different perimeters or algorithm is difficult in judging progression.

### Visual Field Testing and Glaucoma Diagnosis

Visual field testing is critical in the diagnosis of glaucoma. Because of the wide variation in the appearance of the optic disc, it is often difficult to be certain that a patient has glaucoma based on a single observation of the disc in time. Even patients with a cup-to-disc ratio of 0.9 may not have glaucoma. Changes in the optic disc appearance in the form of focal or diffuse loss of neuroretinal rim resulting in an increase in the cup, while diagnostic for glaucoma, generally take years to develop. It is difficult to document this change without serial stereoscopic photographs of the optic disc. Even with optical coherence tomography (OCT), there can be intra- and intersession variability, which makes diagnosis and evaluation for progression challenging. For these reasons, testing visual function with the visual field is a helpful diagnostic tool, although perhaps less sensitive than observed changes to the optic disc or retinal nerve fiber layer, at least with standard white-on-white perimetry. However, in severely cupped nerves, structural identifiers of progression may be nearly impossible to discern, thus placing a much large burden for determining progression on perimetry.

Box 10.5.1 provides a guideline for minimal abnormality on a visual field required to make the diagnosis of glaucoma by SAP. The first two criteria, abnormal glaucoma hemifield test and pattern standard deviation, were used in the Ocular Hypertension Treatment Study (OHTS) as visual field endpoints for the development of primary open-angle glaucoma.<sup>3</sup> The latter criterion, pointwise analysis, may be more sensitive to very early defects. If any of the three criteria listed are present in the absence of other causes—such as nonglaucomatous optic neuropathies or posterior segment pathology (particularly retinal vascular occlusions)—then the

**Fig. 10.5.1 Early Paracentral Scotoma From Glaucoma.** A cluster of three or more points in the expected area of the visual field, all with  $P$  values  $<5\%$ . MD, Mean deviation; PSD, pattern standard deviation.

#### BOX 10.5.1 Minimal Abnormality for Glaucomatous Visual Field Defect<sup>9</sup>

- Abnormal glaucoma hemifield test
- Pattern standard deviation abnormal at  $P < 5\%$  level
- Cluster of 3 or more points on pattern deviation plot abnormal at  $P < 5\%$  level, at least 1 at the  $P < 1\%$  level in an expected area of the visual field

If any one of the above criteria is met, glaucoma should be suspected provided that the visual field defect is repeatable on a second visual field test in a similar location and is not attributable to other pathological findings such as nonglaucomatous optic neuropathy or chorioretinal disease.

From Hodapp E, Parrish RK, Anderson DR. Clinical decisions in glaucoma. St Louis: Mosby; 1993.

#### BOX 10.5.2 Characteristics of Glaucomatous Visual Field Defects

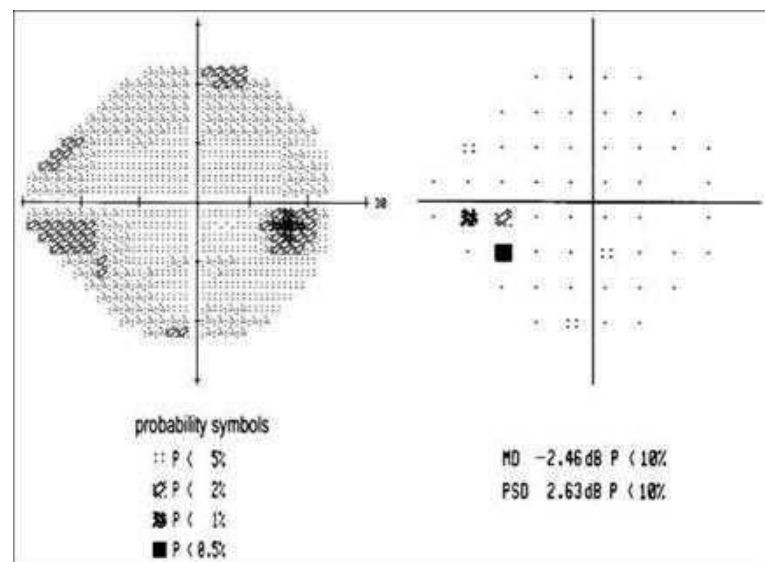

- Almost always localized
- Respect horizontal meridian
- Begin nasal to the blind spot
- Almost always detectable within the central  $30^\circ$

diagnosis of glaucoma should be considered. Typically, but not always, there will be corresponding thinning of the nerve fiber layer or cupping of the optic nerve that correlates well with the defect found on the visual field. False-positive testing in glaucoma suspects and ocular hypertensives has been found to be fairly common, so repeat testing of a suspected early visual field defect is important before concluding that glaucoma is present. In the OHTS, for instance, 86% of suspected new visual field defects disappeared on repeat testing.<sup>4</sup>

Although diffuse depression of the visual field may rarely occur as an early change in glaucoma,<sup>5</sup> most defects are localized, taking the form of a paracentral scotoma (Fig. 10.5.1) or nasal step (Fig. 10.5.2). The best place to look for early glaucomatous visual field defects is the pattern deviation plot rather than the graytone printout or total deviation plot. As glaucoma progresses, these defects typically enlarge and coalesce into arcuate defects corresponding to thinning of the retinal nerve fiber layer. Characteristics typical of glaucomatous visual field defects are listed in Box 10.5.2. Types of glaucomatous visual fields are listed in Box 10.5.3.

### Visual Field and Assessing the Severity of Glaucoma

The severity of visual field defects can be used to assess functional damage to the visual system from glaucoma. This is important to determine the

**Fig. 10.5.2 Early Nasal Step From Glaucoma.** The cluster criterion is met.

#### BOX 10.5.3 Types of Visual Field Defects Commonly Seen in Glaucoma Patients

- Nasal step
- Arcuate defect
- Altitudinal defect
- Paracentral defect
- Temporal wedge
- Generalized depression

aggressiveness of initial therapy (the worse the visual field, the greater the need for intraocular pressure lowering) and to assess the success of ongoing treatment. (Patients who go from moderate to severe visual field defect under treatment, for example, might require more aggressive therapy.)

There are several visual field severity grading scales, including those used in the Advanced Glaucoma Intervention Study,<sup>6</sup> the Collaborative Initial Glaucoma Treatment Study,<sup>7</sup> the Glaucoma Staging System developed by Brusini and colleagues,<sup>8</sup> and the Hodapp–Anderson–Parrish system.<sup>9</sup> We prefer to use an expanded version of visual severity scale proposed by Hodapp, Anderson, and Parrish shown in Table 10.5.1 for the Humphrey Field Analyzer and Table 10.5.2 for the Octopus perimeter.<sup>10</sup> This scale is easy to use in clinical practice, captures the full range of stages in glaucoma progression, and is based on three distinct features of the visual field that should be assessed when deciding on the severity of the functional loss, which include the size of the defect, the depth of the defect, and the proximity of the defect to fixation. It is important to note that all of these severity scales are arbitrary and are not validated by correlation with the severity of axonal loss in the retinal nerve fiber layer—but they serve as important tools in assessing the severity of functional loss in glaucoma.

Figs. 10.5.1 and 10.5.2 are both examples of early visual field defects. Figs. 10.5.3 and 10.5.4 are examples of moderate visual field defects. Figs. 10.5.5 and 10.5.6 are examples of advanced and severe visual field defects, respectively. The pattern of visual field progression in glaucoma from early to severe is predictable in light of the pattern of thinning of the retinal nerve fiber layer, which usually begins with the superior and inferior arcuate fibers, then the papillomacular bundle, and finally the nasal fibers. When the arcuate fibers are lost, the visual field shows only the central and temporal islands remaining, which correspond to the remaining papillomacular and nasal fibers. The next fibers to be lost are typically the papillomacular fibers, which results in central visual acuity loss and eccentric fixation.

In very severe glaucoma, when the majority of the points are depressed to 15 dB or less, special testing is helpful. Fig. 10.5.6 is an example of a visual field defect that is so severe that it is impossible to tell whether points are worsening because most of the values are 0 dB. Increasing to a size V stimulus, retesting the visual field with a size III stimulus using the 10–2 program (thus testing many locations within the central  $10^\circ$ ), or using the macula test (which double determines 16 points in the central  $5^\circ$  using a size III stimulus) are three ways of improving the chance of determining

whether the visual field is worsening in such a patient. Increasing the stimulus size from size III to a size V increases the patient’s ability to see the stimuli and therefore increases the dynamic range of possibilities for responses, thus making progression more easily detected. One can even perform a 10° field with a size V stimulus. Fig. 10.5.7 shows visual field testing performed using these methods in the same patient with severe glaucoma. As a last resort, Goldmann kinetic perimetry may be employed in patients with severe visual field defects, although few offices still have the equipment or technical expertise to perform these tests.

While 10–2 testing strategies have been used traditionally in severe glaucoma, the testing strategy can be used at any stage of the disease. In a review of 35 patients with mild glaucomatous damage, Ancil and Anderson

describe decreased foveal sensitivity in 15 of these patients.<sup>11</sup> Testing the central 10° of vision inpatients with pre-existing paracentral glaucoma has been shown to detect progression at a higher rate than continuing with standard 24–2 testing strategies. Focused testing on the central 10° can aid in glaucoma diagnosis and longitudinal surveillance for progression.<sup>12</sup>

Visual Field and Assessing Progression in Glaucoma

Glaucoma progression is due to the death of retinal ganglion cells and their axons, which usually results in peripheral—followed by central—vision

TABLE 10.5.1 Visual Field Severity Grading System for the Humphrey Visual Field Analyzer (Stages 0–5) <sup>a</sup>	
Stage 0: No or Minimal Defect/Ocular Hypertension	
Does not meet any criteria for stage 1	
Stage 1: Early Defect	
MD ≤−6.00 dB and at least one of the following:	
A	On pattern deviation plot, there exists a cluster of 3 or more points in an expected location of the visual field depressed below the 5% level, at least 1 of which is depressed below the 1% level
B	Corrected pattern standard deviation/pattern standard deviation significant at $P < 0.05$
C	Glaucoma hemifield test “outside normal limits”
Stage 2: Moderate Defect	
MD of −6.01 to −12.00 dB and <i>at least one of the following</i> :	
A	On pattern deviation plot, greater than or equal to 25% but fewer than 50% of points depressed below the 5% level, and greater than or equal to 15% but fewer than 25% of points depressed below 1% level
B	At least 1 point within central 5° with sensitivity of <15 dB but no point within central 5° with sensitivity of <0 dB
C	Only 1 hemifield containing a point with sensitivity <15 dB within 5° of fixation
Stage 3: Advanced Defect	
MD of −12.01 dB to −20.00 dB and <i>at least one of the following</i> :	
A	On pattern deviation plot, greater than or equal to 50% but fewer than 75% of points depressed below the 5% level and greater than or equal to 25% but fewer than 50% of points depressed below 1% level
B	Any point within central 5° with sensitivity of <0 dB
C	Both hemifields containing a point(s) with sensitivity <15 dB within 5° of fixation
Stage 4: Severe Defect	
MD of −20.00 dB and at least one of the following:	
A	On pattern deviation plot, greater than or equal to 75% of points depressed below the 5% level and greater than or equal to 50% of points depressed below 1% level
B	At least 50% of points within central 5° with sensitivity of <0 dB
C	Both hemifields containing greater than 50% of points with sensitivity <15 dB within 5° of fixation
Stage 5: End-stage Disease	
Unable to perform Humphrey visual fields in “worst eye” due to central scotoma or “worst eye” visual acuity of 20/200 or worse due to primary open-angle glaucoma. “Best eye” may be any stage.	
MD, Mean deviation. From Mills RP, Budenz DL, Lee PP, et al. Categorizing the stage of glaucoma from pre-diagnosis to end-stage disease. Am J Ophthalmol 2006;141:24–30.	

Fig. 10.5.3 Moderate Inferior Arcuate Visual Field Defect From Glaucoma.

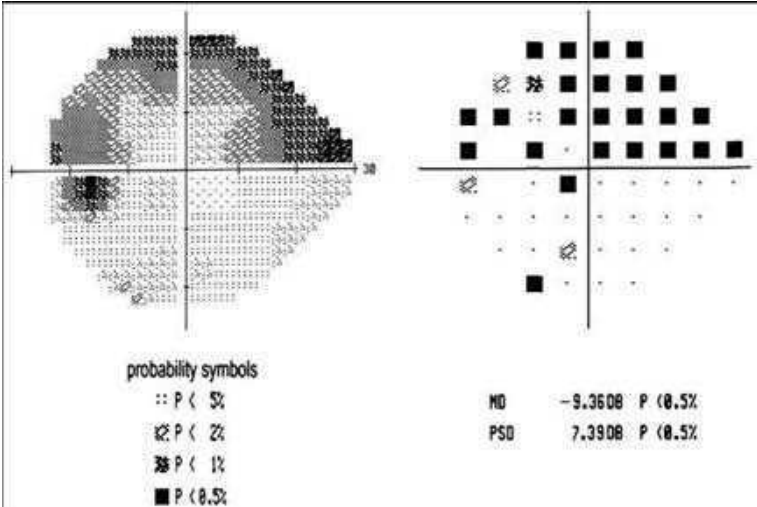

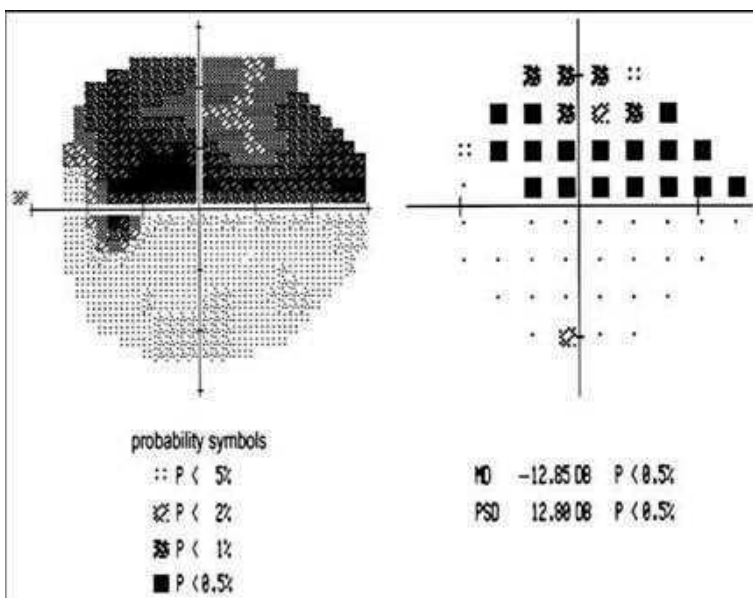

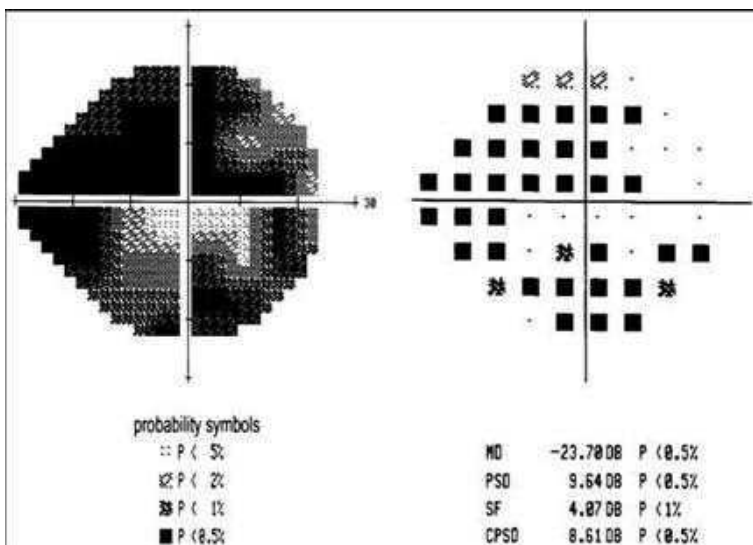

Fig. 10.5.4 Moderate Superior Arcuate Defect From Glaucoma Splitting Fixation.

TABLE 10.5.2 Visual Field Severity Grading System for the Octopus Perimeter (Stages 0–5)		
Stage	Octopus MD Score	Probability plot/pattern deviation The N-Value in the Bebie Curve up to 50 (up to 100) Where the Lower Confidence Limit Line Intersects with the Patient Line
Stage 0: Ocular hypertension/earliest glaucoma	≤−.08	51 and above (101 and above)
Stage 1: Early glaucoma	−0.7 to +4.4	41–50 (81–100)
Stage 2: Moderate glaucoma	+4.5 to +9.5	31–40 (51–80)
Stage 3: Advanced glaucoma	+9.5 to +15.3	21–30 (41–50)
Stage 4: Severe glaucoma	+15.4 to +23.1	11–20 (21–40)
Stage 5: End-stage glaucoma/blind	≥+23.2	≤10 (≤20) or Octopus VF not possible attributable to scotoma in “worst” eye or “worst” eye with acuity of 20/200 or worse due to glaucoma
MD, Mean deviation; VF, visual field. If probability plot is in a less severe stage than preliminary MD stage, then qualify VF as a less severe stage If probability plot is in a more severe stage than preliminary MD stage, then qualify VF as a more severe stage If no intersection of patient line and lower confidence limit, must qualify VF as one stage more than preliminary MD score From Mills RP, Budenz DL, Lee PP, et al. Categorizing the stage of glaucoma from pre-diagnosis to end-stage disease. Am J Ophthalmol 2006;141:24–30.		

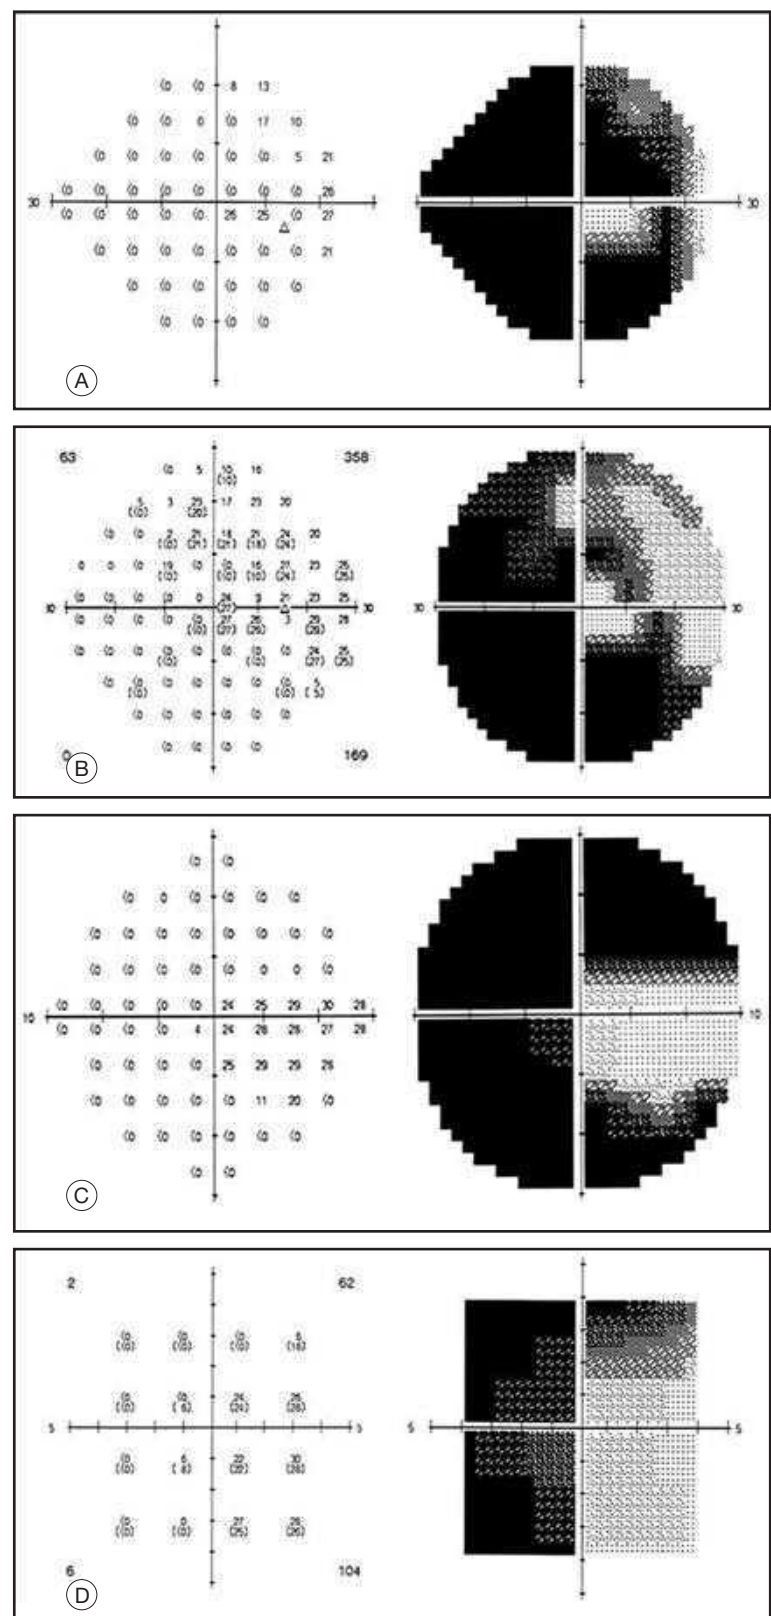

**Fig. 10.5.5** Severe Superior Arcuate Defect Splitting Fixation. Note temporal sparing.

**Fig. 10.5.6** Visual Field of the Left Eye of a Glaucoma Patient. Severe double arcuate scotomas have left the patient with central and temporal islands of vision only. Temporal sparing is common in end-stage glaucoma, which may help distinguish this type of field defect from those associated with nonglaucomatous optic neuropathies.

loss. Assessment of changes in the visual field, optic disc, and retinal nerve fiber layer are the primary ways one diagnoses progression in glaucoma. It is generally believed that structural changes in the optic nerve and retinal nerve fiber layer can be detected before functional changes with SAP, although the Early Manifest Glaucoma Trial found all of their progressive cases except one with SAP rather than optic disc photographs evaluated with flicker chronoscopy.<sup>13</sup> It is possible that with more sensitive functional testing, such as short wavelength automate perimetry, frequency-doubling technology, and pattern electroretinography, functional changes may be found concurrently with structural changes. More research is needed in this area. In clinical practice, following SAP for signs of change is critical in the management of glaucoma and is typically performed every 6–12 months, or more frequently if glaucoma is poorly controlled or rapidly progressive.<sup>14</sup>

There are several ways in which a visual field defect can progress in glaucoma. In the rare case that diffuse depression of the visual field is the only type of field defect, the diffuse depression can get worse or show signs of a new localized defect within the diffuse depression. Localized defects can enlarge or deepen, and finally a new distinct localized defect can appear. In the latter case, the cluster criteria described in [Box 10.5.1](#) are used. When looking for enlarging or deepening of existing defects, one can apply numerical pointwise criteria such as are used in the Collaborative

**Fig. 10.5.7** Advanced Visual Field Testing in a Patient With Severe Glaucoma. The initial visual field, performed using the 24-2 program with a size III stimulus, is so severely depressed that there are too few points to follow for future progression (A). Increasing the stimulus to size V provides more points for comparison and quadrant totals (B), although there are no specific recommendations on what constitutes significant change on visual fields performed with size V stimuli. (C) 10-2 program performed on the same patient as in parts A and B, which tests a size III stimulus within the central 10°. Focusing on the central 10° has increased the number of useful points to follow compared to the central 24° in part A. (D) Performed with the macula test, which double determines 16 points in the central 5° and provides quadrant totals.

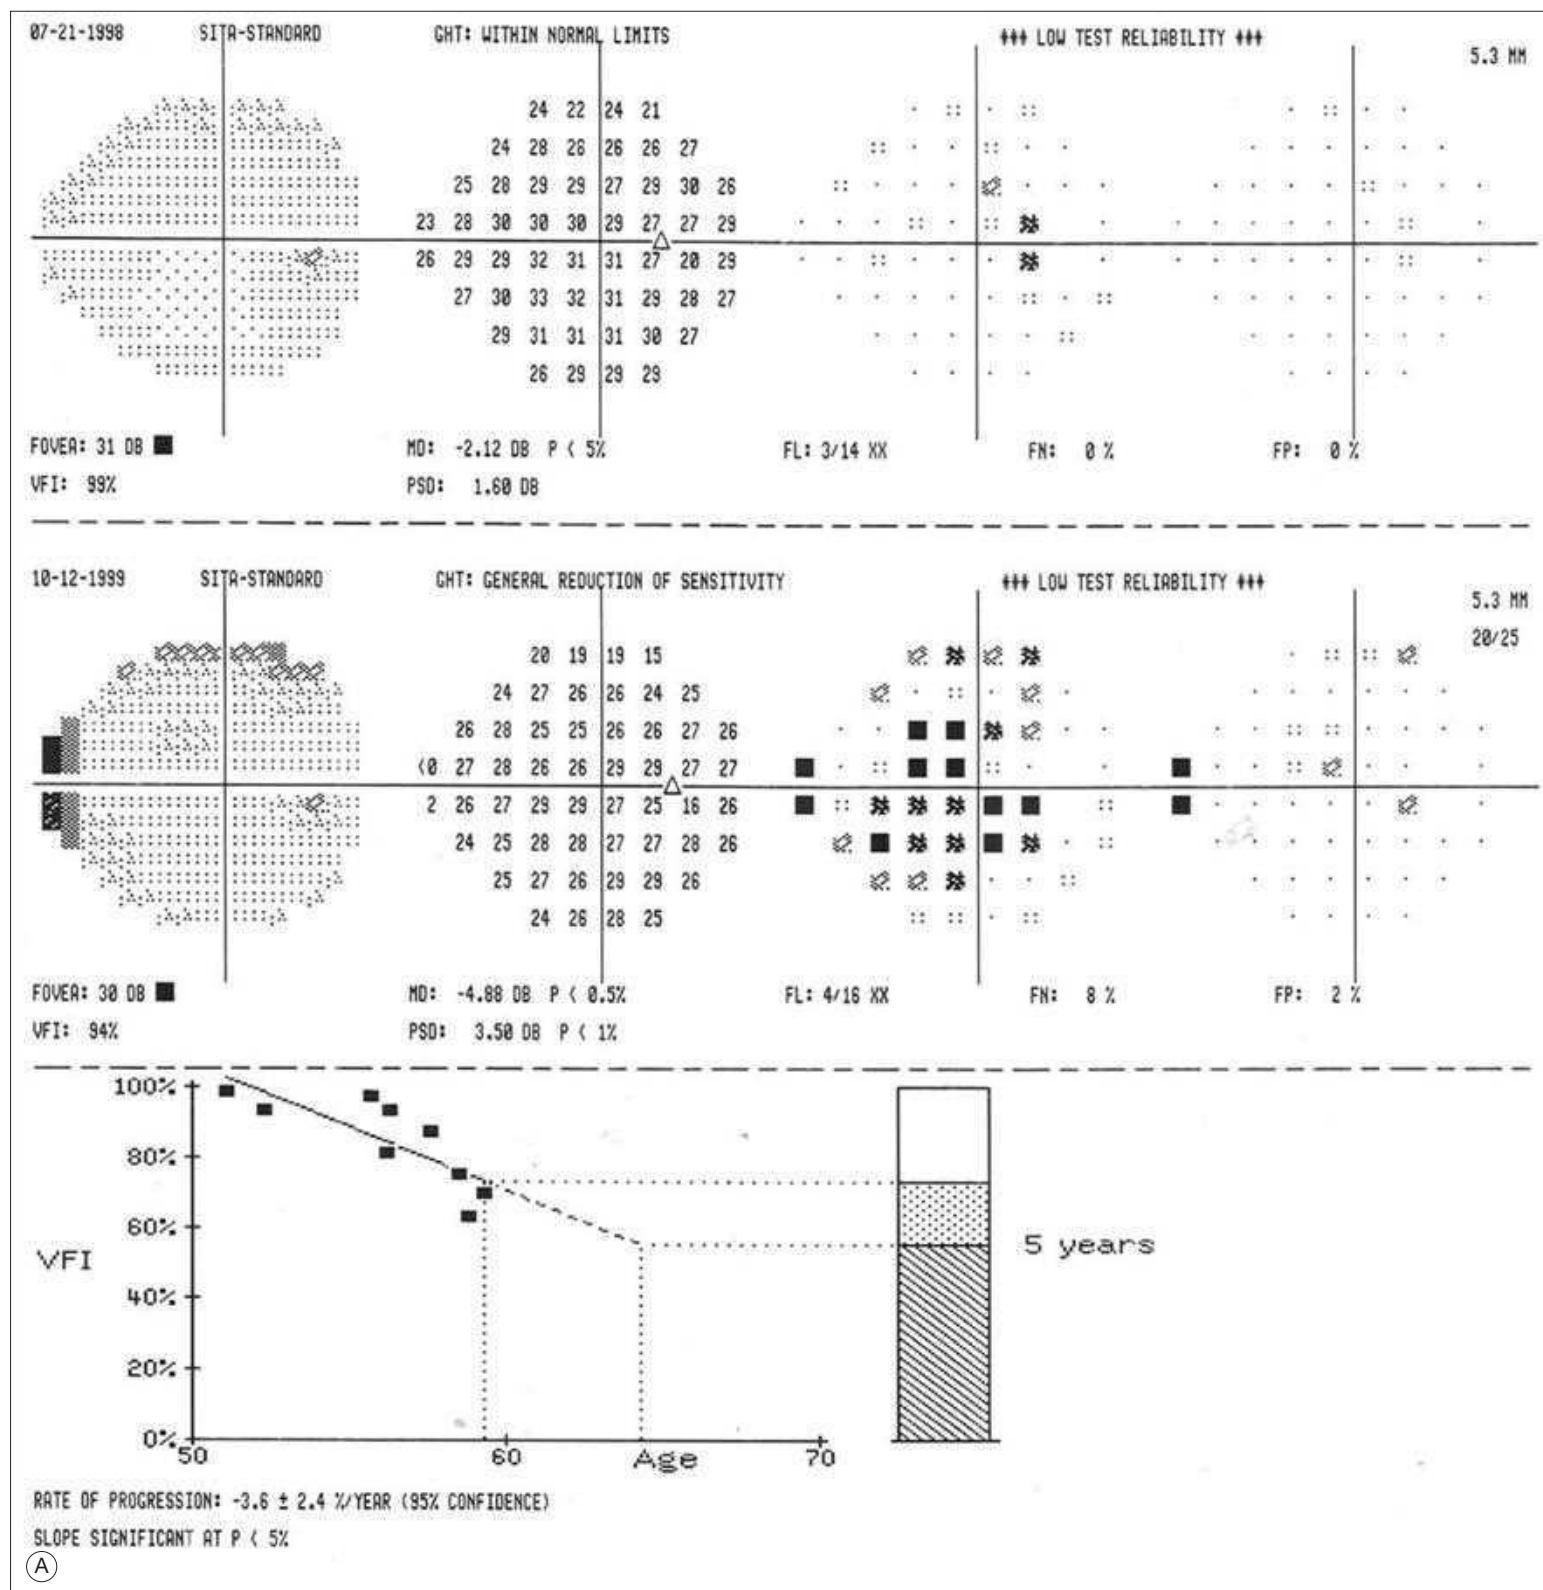

Normal-Tension Glaucoma Study<sup>15</sup> (Table 10.5.3) or one of several statistical programs that analyze individual points, such as the Guided Progression Analysis program for the Humphrey Visual Field Analyzer (Fig. 10.5.8; Zeiss Meditec, Dublin, CA) or the Progressor Programme.<sup>16</sup> Using the global indices, such as worsening of the mean deviation (MD) and pattern standard deviation (PSD), can be difficult for several reasons. The MD is a single measure of the depression of the patient's visual field compared to age-matched controls. It may be getting worse from localized or diffuse changes, the latter most commonly a manifestation of cataract worsening. If the MD and PSD are both worsening, this is better evidence of worsening of a localized defect such as commonly occurs in glaucoma.

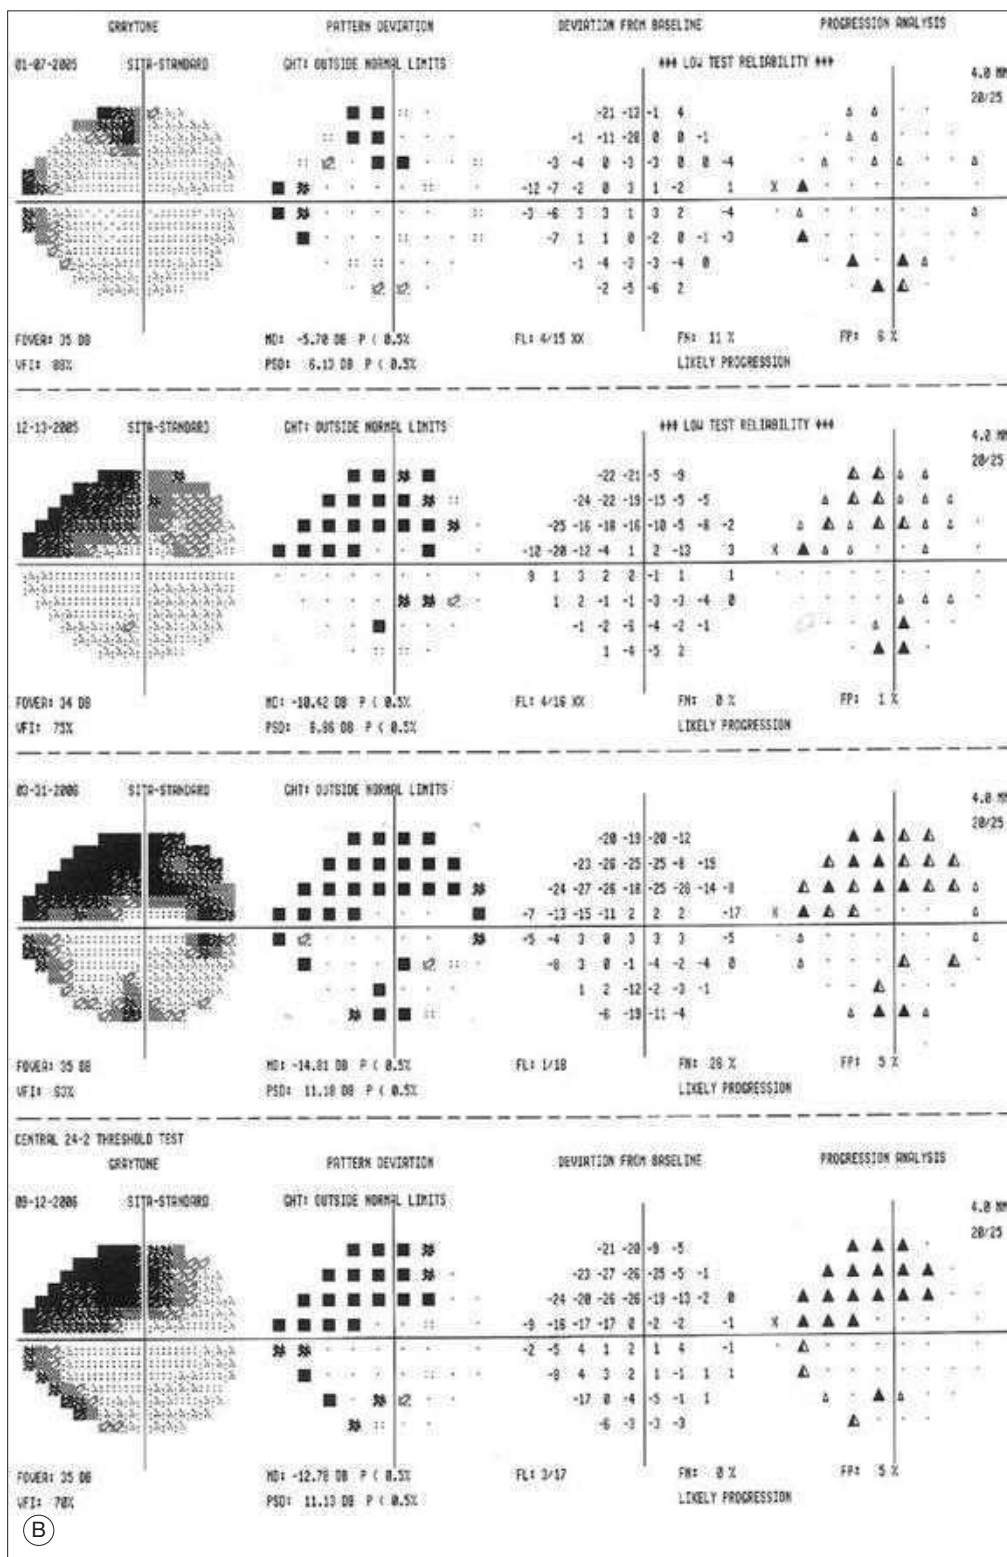

TABLE 10.5.3 Criteria for Judging Glaucoma Progression

Point-wise comparison <sup>15</sup> (Normal-Tension Glaucoma Study)	Defect has deepened or enlarged if 2 or more points within or adjacent to an existing scotoma have worsened by at least 10 dB or 3 times the average of the short-term fluctuations, whichever is larger
Glaucoma progression analysis <sup>17</sup>	Deterioration of 3 or more points at the same location at the $P < 5\%$ level on 3 consecutive visual fields
Regression analysis of mean deviation	Deterioration of slope of mean deviation at the $P < 5\%$ level per year

All criteria assume confirmation on at least 1, and better yet 2, subsequent field and clinical correlation with no other explanation for deterioration.

**Fig. 10.5.8 Glaucoma Progression Analysis.** Visual fields of the right eye of a glaucoma patient analyzed with the Glaucoma Progression Analysis program. (A) shows the two baseline visual fields that are merged for future comparison as well as the Visual Field Index (VFI). The plot of VFI (X-axis) by age (Y-axis) indicates deterioration of visual field function from nearly 100% at age 51 and 75% at age 59. The trend line continues another 5 years and predicts a decline to 60% VFI by age 64 if the progression is not slowed by more aggressive therapy.

**Fig. 10.5.8, cont'd** (B) shows follow-up visual fields with numerous half- and fully darkened triangles indicating significant change at these points on repeat testing. The follow-up fields all give "Likely Progression" messages because three or more points have worsened in the exact same location on at least three follow-up fields (intervening fields not shown).

The pattern deviation value is not the best measure of a worsening visual field in glaucoma, however, because it gets higher initially in glaucoma but then lower as more and more of the visual field becomes affected.

Guided Progression Analysis (GPA) is based on test-retest data and was used in the Early Manifest Glaucoma Trial.<sup>17</sup> The GPA software analyzes the change in a patient's visual field results from two baseline fields to the current visual field. If the change at an individual point has less than a 5% probability of falling within the range considered to be noise, that change is counted as "possible progression." Of course, at this level of statistical significance, we would expect one in 20 patients to produce a false positive at any particular point. But the program requires that three or more of the same points show change on three consecutive fields before the message "Likely Progression" is displayed. A new global index available for the Humphrey Visual Field Analyzer, the Visual Field Index (VFI), provides a measure of the percentage of visual field remaining, from 0%

(perimetrically blind) to 100% (full visual field function).<sup>18</sup> VFI differs from MD, the traditional global index for following perimetric function over time, in that it uses the pattern deviation probability values rather than the total deviation probability values in an attempt to reduce the effect of cataract on the index. Additionally, it weights defects closer to fixation higher than those away from fixation. VFI provides trend analysis, as opposed to the event analysis provided by GPA, by plotting VFI graphically. The advantage of VFI is that one can determine the rate of visual field progression to date and then predict how much additional visual field function would be lost over the subsequent 5 years if there were no change in the rate of loss. Fig. 10.5.8 is an example of the GPA and VFI analyses in a patient with progressive glaucoma. It is important to differentiate real glaucomatous visual field change from artifactual change. Long-term fluctuation is the most common reason for a false-positive follow-up field in glaucoma but can be minimized by repeat testing. It cannot be stressed enough that

any suspected change on the visual field must be confirmed on two subsequent visual fields before concluding that the field is truly worse.<sup>15</sup>

As mentioned previously, even under ideal testing circumstances, fluctuations in visual fields are common. It is of paramount importance to always evaluate the reliability of the visual fields (false positives, false negatives, and fixations losses) and to communicate with the tester to determine if there was cooperation of the patient with the test. Artifacts in visual field testing, such as lens rim artifact, use of an incorrect corrective lens, testing the incorrect eye, entering an incorrect date of birth, miotic pupil, eyelid position, or incorrect fixation, must be ruled out as well. Conditions other than glaucoma can mimic glaucomatous progression, so a complete and careful examination looking for, particularly, retinal or nonglaucomatous optic neuropathies and central nervous system-type defects should be undertaken before glaucoma is blamed for progression on the visual field.

# Advanced Psychophysical Tests for Glaucoma

## 10.6

Chris A. Johnson

**Definition:** Threshold estimation strategies, test procedures, and analysis methods provide improvements in the accuracy, sensitivity, and reproducibility of perimetry and visual field testing.

### Key Features

- Swedish Interactive Threshold Algorithm.
- Zippy Estimation by Sequential Thresholds.
- Tendency-oriented perimetry.
- Dynamic strategy.
- Frequency-doubling technology.
- Matrix perimetry.
- Pulsar perimetry.
- Rarebit perimetry.
- Heidelberg edge perimetry.
- Tablet-based perimetry.
- Visual field index.
- Guided Progression Analysis 2.

## INTRODUCTION

Evaluation of glaucomatous functional deficits is important for practitioners and investigators. Although color vision, contrast sensitivity, and other psychophysical tests have been used,<sup>1</sup> perimetry remains the primary basis for evaluating glaucomatous visual function. Recent innovations for perimetry have enhanced its utility. This chapter provides a brief review of new test strategies, assessment procedures, and analysis techniques.

## TEST STRATEGIES

Visual field testing initially consisted of detecting a moving target (kinetic) or luminance increment (static) on a uniform background. Automated perimetry introduced the staircase procedure, which was variable and time consuming, so better strategies were developed.

The Swedish Interactive Threshold Algorithm (SITA) incorporates a Bayesian (forecasting) strategy that improves accuracy, efficiency, and reliability.<sup>2-5</sup> SITA uses prior information from normal and glaucoma populations of various ages to determine probability density functions (pdfs) for each location. During testing the pdf is modified until the 95% confidence limits are within acceptable limits (dynamic termination). SITA has better test-retest reliability and reduces testing time by 25%–50% compared to staircase tests. Two strategies are available: SITA Standard and SITA Fast. The SITA Fast procedure allows a larger window of acceptable error, making it a faster test with more variability.

The Zippy Estimation by Sequential Thresholds (ZEST) procedure is a Bayesian strategy similar to SITA, with two differences. First, the pdf is uniform over the range of stimulus intensities, making it less vulnerable to response biases. Second, it uses a fixed number of presentations to estimate threshold, but “suspicious” values are retested.<sup>6-9</sup> Testing time is consistent regardless of the patient’s visual field status or reliability.<sup>7-9</sup>

Tendency-oriented perimetry (TOP) is a strategy based on a spatial averaging staircase.<sup>10,11</sup> TOP provides an efficient evaluation of visual field properties,<sup>10</sup> although it can miss small visual field defects and underestimate the slope of borders of visual field loss.<sup>11</sup>

The dynamic strategy is similar to a staircase, but the size of the change between stimulus presentations is proportional to the current threshold level, whereas the staircase uses fixed changes.<sup>12,13</sup> The dynamic strategy is similar to the modified binary search (MOBS).<sup>12-14</sup> The dynamic strategy reduces test time and response variability by approximately 50%.

These strategies are currently implemented in commercial automated perimeters, and results are often similar.<sup>14</sup>

## TEST PROCEDURES

Frequency-doubling technology (FDT) perimetry presents a low spatial frequency (under 1 cycle per degree) sinusoidal grating undergoing high temporal frequency (over 15 Hz) counterphase flicker.<sup>15-17</sup> The observer detects the FDT stimulus on a uniform background, and the minimum contrast for detection is measured at each location. The original FDT device tested 19 locations within the central 30° radius, with a threshold test procedure in approximately 4 minutes per eye and a rapid screening test in 30–60 seconds per eye. A second generation FDT device, the Humphrey Matrix, has additional features and incorporates several different stimulus patterns for evaluating the central 30° (24–2 and 30–2 tests) and the macula (10–2 and macula tests). These tests provide useful assessments for characterization of glaucomatous visual field loss.<sup>15-17</sup> Fig. 10.6.1 presents an example of the Humphrey Matrix 24–2 test performed on the left eye of a patient with inferior paracentral visual field loss.

Pulsar perimetry is similar to FDT perimetry in that it presents a low spatial frequency sinusoidal grating that undergoes high temporal frequency counterphase flicker.<sup>18-20</sup> However, the sinusoidal grating is two dimensional, with contrast tapered toward the edge of the stimulus. The stimulus appears as a bullseye target radiating outward from the center. Because several spatial and temporal frequency combinations are employed for each stimulus location, the final measure is presented in spatial resolution contrast units (src units). A tendency-oriented perimetry (TOP) test strategy is used.<sup>18-20</sup> Fig. 10.6.2 presents an example of pulsar perimetry obtained for the right eye of an observer with a superior nasal step.

Rarebit perimetry is a suprathreshold test procedure in which small dots (pixels) are presented on a computer monitor.<sup>21-23</sup> For each stimulus presentation, 0, 1, or 2 dots are presented within a small localized visual field region, and the observer indicates whether they observed 0, 1, or 2 dots. It is intended to provide fine detail mapping of the central visual field to identify areas of heterogeneous or “patchy” visual field loss and gaps in overlapping ganglion cell–receptive field areas from glaucomatous damage. For each visual field region, the procedure determines the “hit rate” (percent correct) and “miss rate” (percent incorrect).<sup>21-23</sup> An example of a glaucomatous arcuate visual field defect for the right eye is presented in Fig. 10.6.3.

Heidelberg edge perimetry (HEP) utilizes flicker-defined form. The background and stimulus consist of an array of random dots that are presented on a computer monitor. The dots are flickering at a rapid rate, and a stimulus is generated by rapid counterphase flicker.<sup>24,25</sup> Fig. 10.6.4 presents an example of a superior arcuate glaucomatous visual field defect for a right eye that was evaluated with Heidelberg edge perimetry.

The advent of smartphones and tablets has prompted the development of new visual function test procedures that can be utilized for

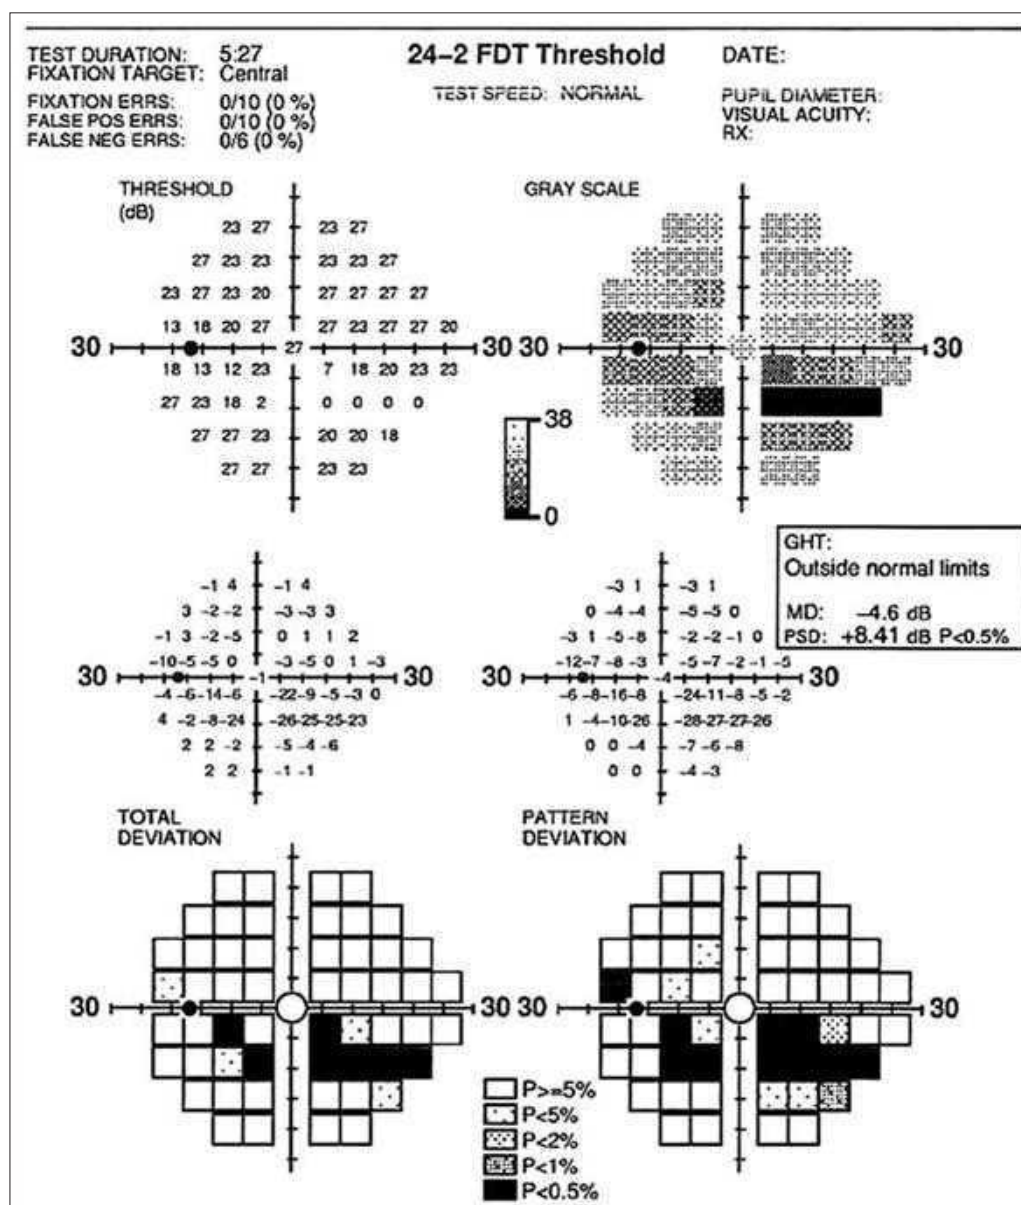

Fig. 10.6.1 Humphrey Matrix Frequency-Doubling Technology (FDT). Results for the left eye of a glaucoma patient with an inferior arcuate visual field defect.

population-based screening, home testing, and evaluation in the waiting room of an eye care specialist's office. Several investigators have developed procedures for visual field screening and quantitative threshold assessment of the central 30° visual field.<sup>26-28</sup> The results compare favorably with the Humphrey Field Analyzer and provide a portable, battery-operated means of performing visual field testing in remote areas, for populations at high risk of developing visual problems, and for those with limited access to traditional health care and eye examinations. It is likely that refinements of this procedure may incorporate virtual reality goggles that could permit testing to be performed while patients are seated in the waiting area before being seen by an eye care specialist.

## ANALYSIS METHODS

Overviews of methods to evaluate visual fields longitudinally and stage glaucomatous visual function loss have been published by many investigators.<sup>29-34</sup>

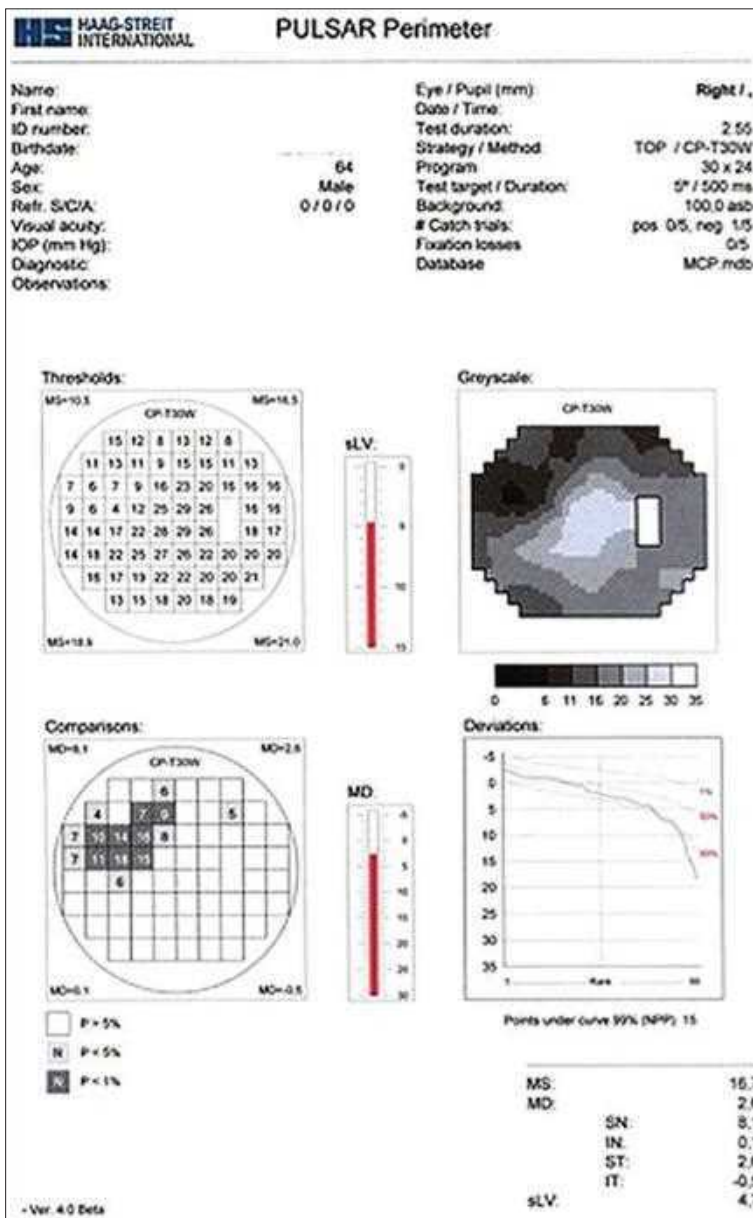

The visual field index (VFI) estimates the rate of change in glaucomatous visual fields over time.<sup>33</sup> It is based on an analysis of mean deviation (MD) but expresses visual field loss as a percentage between 100% (normal) to 0% (blind). To minimize the influence of cataract, the VFI uses

probability values from pattern deviations rather than total deviations and applies greater weight to more centrally located points. The VFI provides a continuous, quantitative assessment of visual field damage. However, it is relatively insensitive to early glaucomatous visual field loss (MD no worse than -6 dB), is more optimistic in its assessment than expert visual field evaluators, and lacks evidence basis to indicate that it is superior or inferior to MD as a measure of visual field damage.<sup>33</sup>

A method that utilizes the VFI is the Guided Progression Analysis 2 (GPA 2).<sup>34</sup> The GPA 2 provides a linear regression of the VFI over time to estimate rate of progression and demonstrates defect depth and probability levels for individual test locations. The GPA 2 provides information concerning glaucomatous visual field progression, it can localize and identify visual field locations with the most change, and printouts can be evaluated and interpreted efficiently and accurately.<sup>35</sup>

Permutation analysis is used for magnetic resonance imaging (MRI) and positron emission tomography (PET) to determine whether variations are systematic, sequential, or due to random variation. It was adapted to ocular imaging<sup>35</sup> and is now applied to visual field analysis. Permutation analysis performs a random shuffle of visual field tests to generate a set of distributions to determine whether the proper chronological sequence of tests provides more effective information.

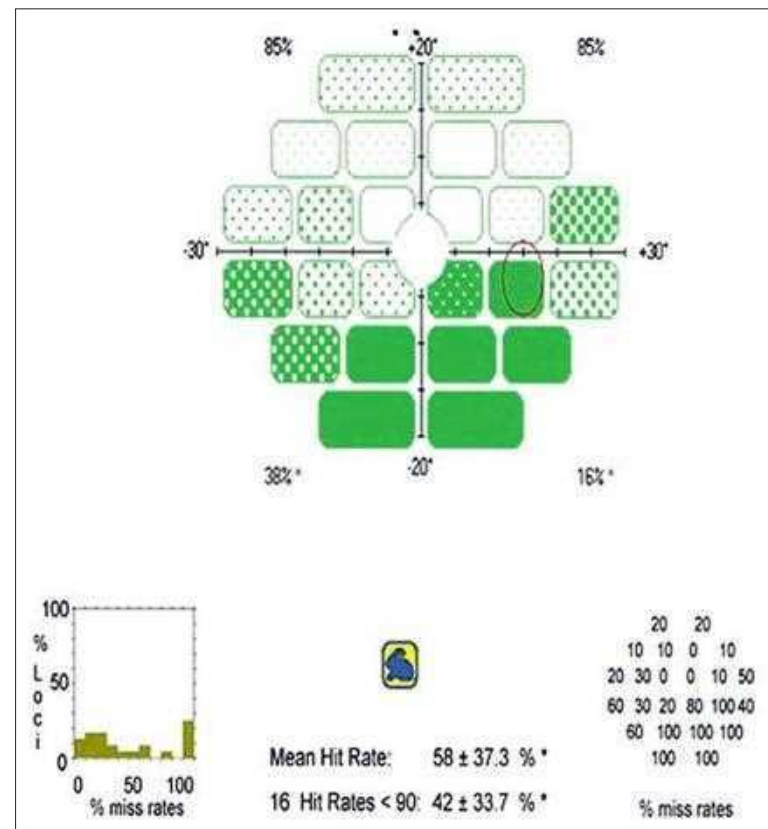

**Fig. 10.6.2 Pulsar Perimetry.** Results for the right eye of a glaucoma patient with a superior nasal step and partial arcuate visual field defect. The values are in spatial resolution contrast (src) units.

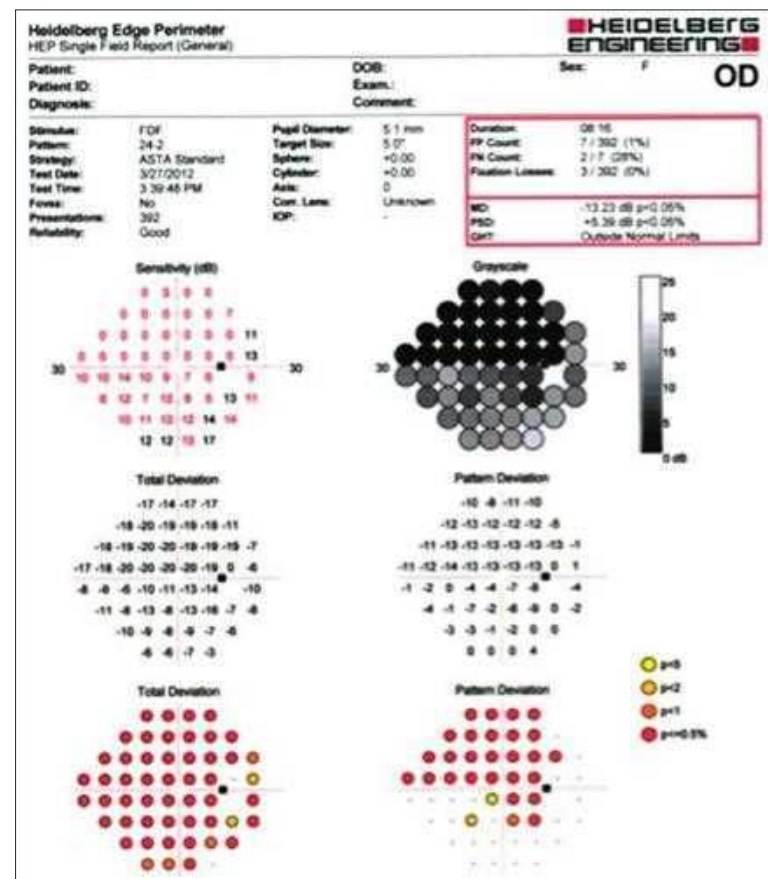

Although there are many different statistical and mathematical models currently being developed and validated for evaluating glaucomatous visual field progression, many of the more sophisticated ones require a large amount of background familiarity, require considerable computational power, and have complex outcomes, which limits their use in a busy clinic. Recently, Gardiner and Demirel<sup>36</sup> compared three common visual field indices: mean deviation (MD), pattern standard deviation (PSD), and visual field index (VFI). They found that MD was able to detect more cases than PSD or VFI and was also able to detect visual field deterioration earlier than the other two indices.

## CONCLUSION

The clinical value of perimetry has significantly improved through the innovative procedures for functional evaluation of glaucoma. Efforts to improve the accuracy and efficiency of testing strategies, develop test procedures that target key mechanisms, and create analysis procedures that combine functional, structural, and clinical information should make detection of glaucomatous damage and progression easier.

**Fig. 10.6.3 Rarebit Perimetry.** Results for the right eye of a glaucoma patient with an inferior arcuate defect and some superior partial arcuate sensitivity loss. The percentage miss rate (100% minus the hit rate) is shown for each visual field region tested.

**Fig. 10.6.4 Heidelberg Edge Perimetry (HEP).** Results for the right eye of a glaucoma patient with a superior arcuate visual field defect. The HEP performs testing using a flicker-defined-form stimulus.

# Optic Nerve Analysis

Gadi Wollstein, Fabio Lavinsky, Joel S. Schuman

# 10.7

**Definition:** Ancillary testing to document the characteristic glaucomatous changes in optic disc morphology, which are critical to the diagnosis and longitudinal management of all forms of glaucoma.

## Key Features

- Focal and/or generalized thinning of the neuroretinal rim.
- Progression of glaucomatous optic neuropathy over time.

## Associated Features

- Blood vessel baring.
- Lamina cribrosa “show”.
- Disc hemorrhage.
- Peripapillary atrophy.
- Retinal nerve fiber layer loss.

## Diagnostic Technologies

- Stereobiomicroscopy.
- Stereo disc photographs (and red-free filter).
- Confocal scanning laser ophthalmoscopy.
- Optical coherence tomography.

## INTRODUCTION

Optic nerve head (ONH) assessment is a crucial part of the glaucoma clinical examination. Owing to the large variability in the ONH features among healthy subjects, the identification of glaucomatous abnormality is challenging, particularly in the early stages of the disease. Nevertheless, it has been suggested that structural glaucomatous abnormalities precede the appearance of functional abnormalities, further emphasizing the importance of disc assessment clinically and with ancillary tools.<sup>1</sup>

## NORMAL ANATOMY

The ONH is composed of neural fibers, blood vessels, glial cells, and other support tissues. The axons, which constitute the major component of the ONH, originate in the retinal ganglion cell somas, traveling in the retinal nerve fiber layer (RNFL) and gathering together from throughout the retina in the ONH (Fig. 10.7.1). This pathway transfers the neural signal from the retina to the visual cortex in the brain. Approximately 1.2 million nerve fibers pass through the ONH, organized into bundles passing through the lamina cribrosa, which provides the structural support to the neural tissue. The total number of nerve fibers passing through the ONH is related to the disc size, with larger discs composed of more fibers compared with smaller discs. The typical healthy disc is oval in shape with the

**Fig. 10.7.1** Optic disc photographs of a healthy left eye optic nerve head with small central cupping (A), and a glaucomatous eye with enlarged cupping, focal neuroretinal rim thinning not respecting the ISNT rule, blood vessel nasalization, lamina cribrosa show, and peripapillary atrophy (B).

long axis vertically oriented. The average diameter of the disc is 1.5 mm and average disc area is 1.8 mm<sup>2</sup>. The optic disc is usually divided into two main structural components: the neuroretinal rim and the disc cup. The rim is the location of all axons, whereas the cup is the space devoid of any axons. The ONH cup is oval shaped and centrally located in healthy eyes, with the long axis horizontally oriented. The perpendicular orientations of the disc and the cup combine to lead to the typical configuration of the rim, where the thickest area is in the inferior quadrant, followed by the superior, nasal, and temporal quadrants (the ISNT rule).<sup>2</sup> In eyes with a larger ONH, the cup can be larger than in eyes with a smaller disc as the remaining area of the rim still allows all axons to pass through. The spatial distribution of the fibers is organized such that the main arcuate bundles of the RNFL enter through the poles and those originating from the posterior pole form the papillomacular bundle entering the temporal aspect of the ONH. Fibers originating in the retinal periphery tend to be located toward the disc margin, whereas fibers originating from the posterior pole tend to be located in the center of the disc. The central retinal artery enters and the vein exits the eye at the center of the ONH and divide into their branches while still within the optic disc area. Circumlinear vessels that leave the central blood vessels' trunk toward the macula can often be observed. These vessels lie superficially and are supported by the rim tissue at the edge of the cup. In up to a third of eyes, a cilioretinal artery can be observed at the temporal periphery of the disc. The typical shape of the ONH described so far can vary markedly between subjects. Common examples of natural variability are an optic nerve that enters the eyeball at a steep angle, so that the disc appears tilted, and myopic eyes with a shallow cup that may be difficult to delineate.

## CLINICAL EXAMINATION: GLAUCOMATOUS FEATURES

### Disc Cup

Several structural features have been associated with glaucomatous damage. The neural tissue loss, which is the hallmark of glaucoma, is seen in the ONH as an enlargement of the cup and thinning of the rim. These changes can occur throughout the disc as global thinning of the rim or as a localized thinning, which is often described as a *rim notch*. The neural loss also leads to deepening of the cup with exposure of the lamina cribrosa at the bottom of the cup. The cup size is often described as the vertical ratio between the cup and disc diameters (cup-to-disc ratio). However, this method is prone to inaccurate estimations, especially in the presence of atypical cups. The disc size should also be taken into account because larger discs can have a larger cup, whereas in smaller discs, even a small cup can represent a substantial level of tissue damage. Disc area can vary among healthy individuals by as much as six times and thus directly affect the outcome of the examination.<sup>2</sup> The disc size can be estimated clinically by adjusting the slit height to the disc margins and reading the measurement scale of the slit lamp after applying the correction factor for the magnifying lens used. The cup-to-disc ratio varies markedly in the population but a ratio greater than 0.65 was found in less than 5% of healthy subjects.<sup>3</sup> The cup tends to be symmetrical between eyes with a difference 0.2 or less in the cup-to-disc ratio observed in greater than 96% of healthy subjects.<sup>2</sup> Therefore, when asymmetry between eyes is noted, the possibility of glaucomatous damage should be considered.

### Blood Vessels

Because the blood vessels are mainly supported by the neural tissue, bends along the blood vessels, especially in the circumlinear vessels, are useful indicators as to the location of the cup margin. As the disease progresses with concomitant neural tissue loss, the trunk of the main blood vessels tends to shift toward the nasal aspect of the disc. In some cases, the vessels remain in an unchanged position, but with loss of tissue support—the so-called “baring of the circumlinear vessels.” Segmental changes in the caliber of the blood vessels, as well as splinter disc hemorrhages, can be noted in some eyes. These hemorrhages are transient and are usually followed by localized rim thinning at the same location, with corresponding visual field abnormality. Although the hemorrhages are not common in glaucomatous eyes, their prevalence in the healthy population is low, and thus the presence of this finding should raise suspicion of ongoing glaucomatous damage.<sup>4</sup> Furthermore, disc hemorrhages are associated with higher likelihood of glaucoma progression.<sup>5</sup>

## Peripapillary Atrophy

A common sign in glaucoma is the appearance of atrophic changes adjacent to the disc margin. Hyperpigmented or hypopigmented atrophy (also known as the *alpha zone*) and, in many cases, both types of atrophy are present side by side. The atrophy is not specific for glaucoma and appears in other ocular conditions. However, the appearance of a central area of atrophy of the retinal pigment epithelium and the choriocapillaris close to the disc (*beta zone*) has been shown to occur with high prevalence in glaucomatous eyes.<sup>6</sup>

## IMAGING

The introduction of imaging devices for ONH evaluation allows for an objective documentation and quantification of this region of the eye. Given the considerable variation in ONH appearance among healthy subjects, the various patterns of glaucomatous cupping, and the wide variation in the assessment of ONH appearance among examiners from visit to visit, it can be very difficult to make consistent decisions. Moreover, because the glaucomatous changes progress slowly, these quantitative modalities allow detection of minute changes that are difficult to observe during clinical examination. This, in turn, improves glaucoma detection and might also improve the ability to identify glaucoma progression over time, influencing management and decision making for subjects with glaucoma.

## OPTIC DISC PHOTOGRAPHY

Stereoscopic ONH photography is currently a commonly used technology to document disc appearance. It is performed by using either consecutive photographs after a manual shift of the camera or simultaneously acquired photographs with a fixed base distance. The photography provides the structural information in the most intuitive way for the clinician, acquisition is rapid and images are highly detailed (see Fig. 10.71). This method also allows for recording of various features, such as hemorrhages, that can only be appreciated by a human examiner. Although the photograph itself is an objective record, this method requires subjective interpretation, which is highly dependent on the examiner's skills and has high variability among examiners. Numerous studies have demonstrated similar ability for discrimination between healthy and glaucomatous eyes by expert assessment of ONH photographs and imaging devices.<sup>7,8</sup> However, when detection of glaucoma progression was compared between assessment of consecutive ONH photographs and visual field tests, a poor agreement was noted between the two methods.<sup>9</sup> This discrepancy might reflect the temporal differences between structural progression and functional progression. As glaucoma assessment typically requires both aspects, the appearance of a lag between progression of structure and of function complicates the ability to detect glaucoma progression.

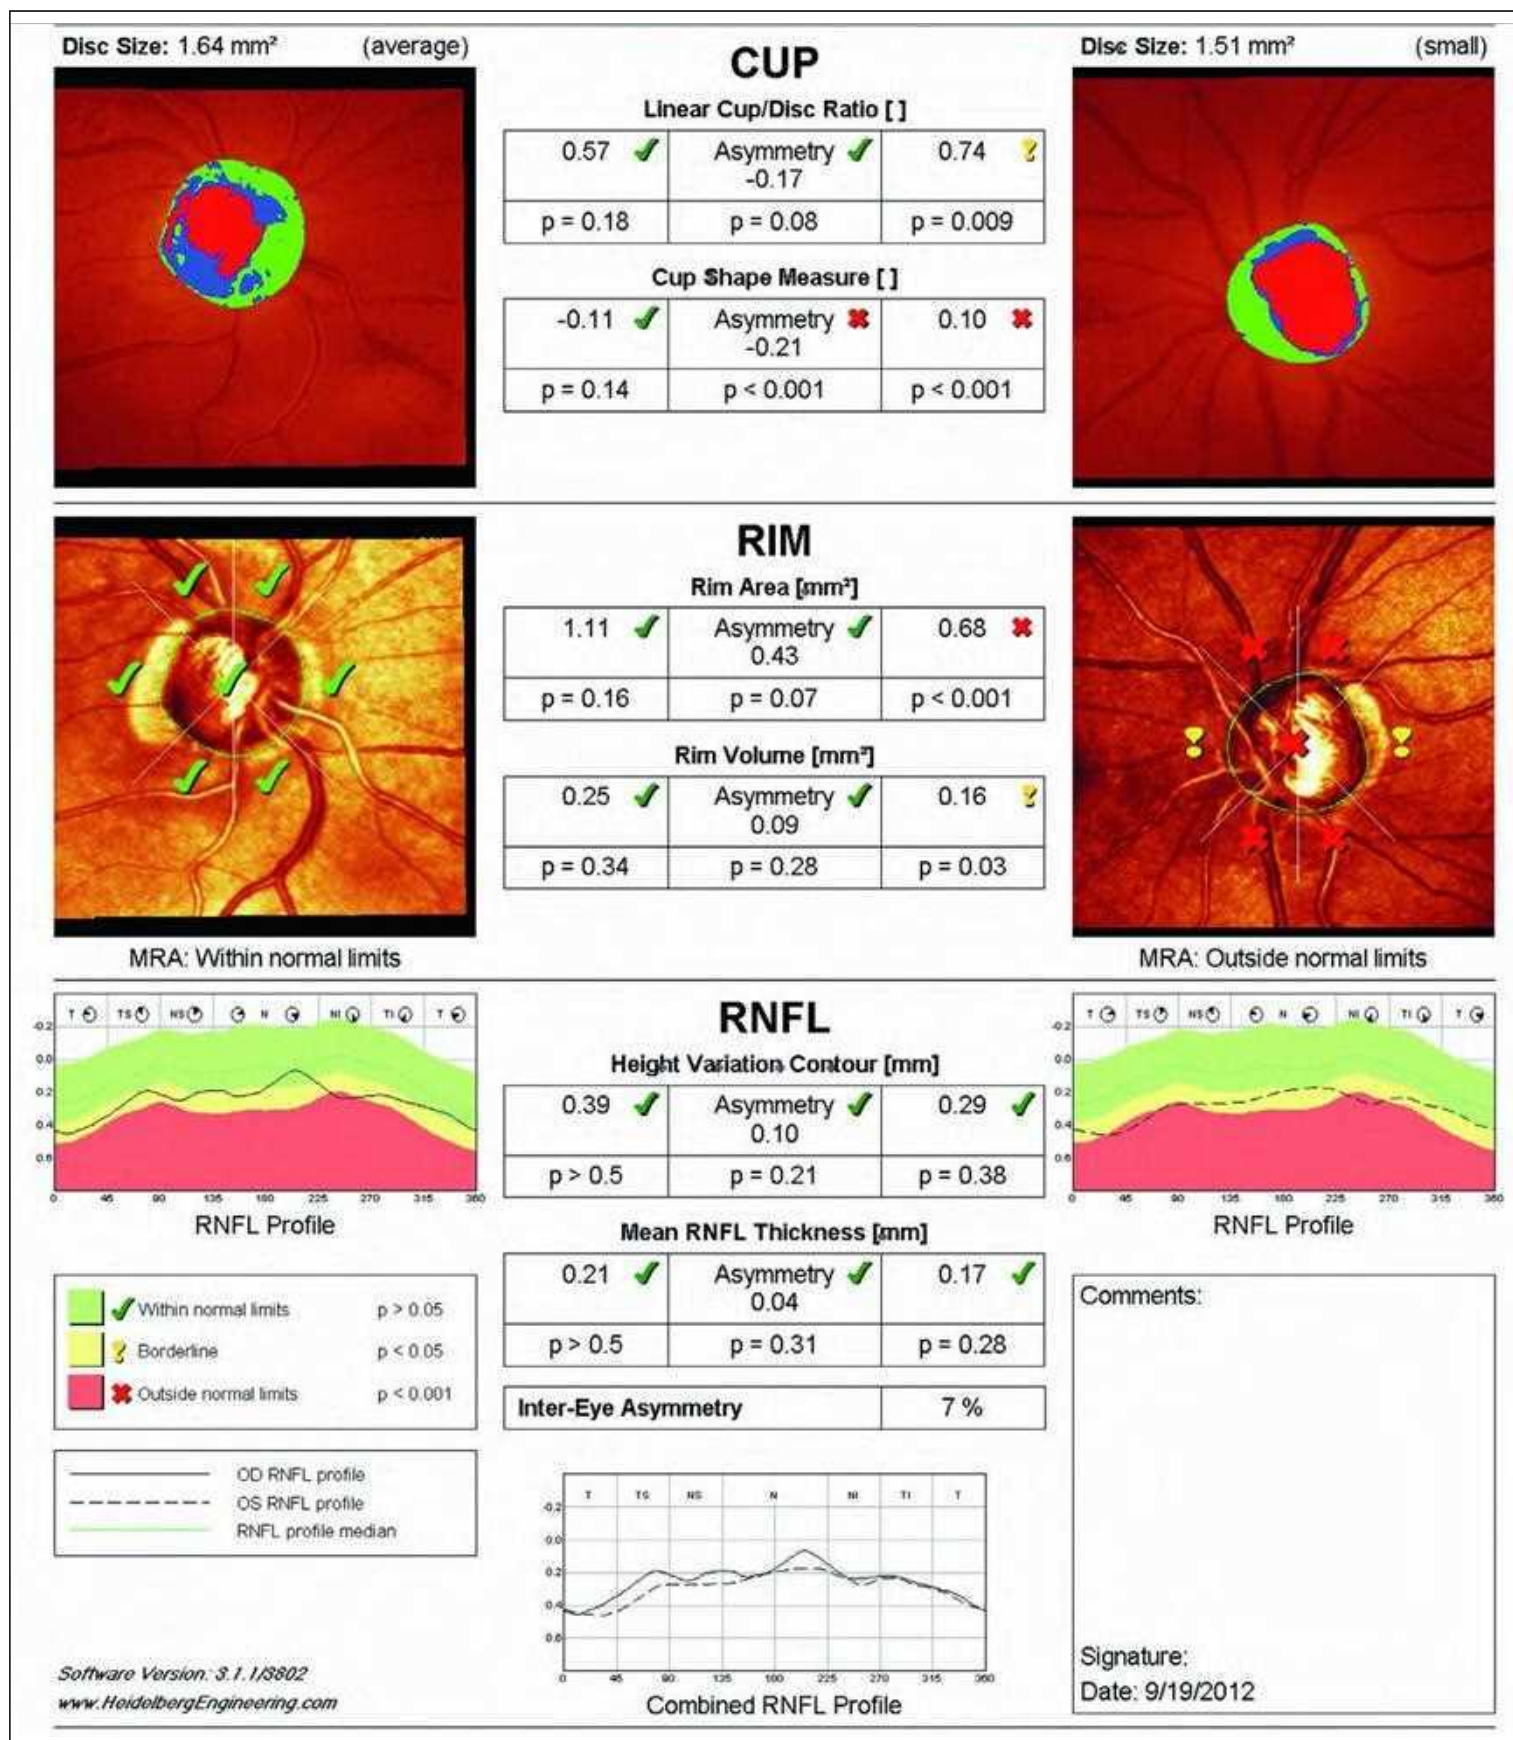

## CONFOCAL SCANNING LASER OPHTHALMOSCOPY

Confocal scanning laser ophthalmoscopy (CSLO) technology is based on the principle that light projected toward the plane of interest through a conjugated set of pinholes allows light to reach the detector only from the desired plane, whereas light coming from all other locations is blocked. The device acquires multiple scans at parallel planes and thus enables the three-dimensional reconstruction of the scanned region. The Heidelberg Retina Tomograph (HRT; Heidelberg Engineering, Heidelberg, Germany) is a CSLO device that was designed to scan the ONH region. It uses a diode laser as the light source (wavelength: 670 nm) to acquire a stack of parallel ONH scans that start anterior to the ONH and end posterior to the bottom of the optic cup. The machine identifies the location of the highest level of reflected light throughout the stack of scans for each pixel, which corresponds to the location of the vitreoretinal interface. The transverse resolution of the HRT is 10 μm with axial resolution of 300 μm.

Numerous studies have reported that HRT measurements are highly reproducible<sup>10</sup> and have provided the ability to discriminate between healthy and glaucomatous eyes.<sup>11,12</sup> The best discriminative parameters are cup shape measure, rim area, and cup volume, although considerable overlap exists between healthy and glaucomatous eyes (Fig. 10.72). Improved discrimination is achieved when several HRT parameters are combined.

The Moorfields regression analysis, which is part of the HRT software, adjust the rim area for the subject's global disc size and in predefined

**Fig. 10.7.2** Heidelberg Retina Tomograph report of healthy (right eye) and glaucomatous (left eye) eyes. The upper panel is a topographic image overlaid with the neuroretinal rim (green and blue) and cup (red) marking. The reflectance map (middle image) provides an image similar to the appearance observed when examining the eye. The optic nerve head margin is marked with the green line. Moorfields regression analysis results are overlaid on the image with check marks denoting all sectors and global measurements are within normal limits in the healthy eye (left column), and most sectors are borderline and outside normal limits (yellow and red markings, respectively) in the glaucomatous eye (right column). The retinal nerve fiber layer thickness profile surrounding the optic nerve head appears at the bottom with comparison to the population derived normal range. Stereometric parameters and the symmetry of measurements between the eyes (center column) show abnormal cup and rim measurements in the glaucomatous eye.

sectors, thus enabling the detection of focal as well as global abnormalities. This method has been reported to provide good discrimination between healthy and glaucomatous eyes.<sup>13,14</sup> The device also includes the Glaucoma Probability Score (GPS), which automatically obtains structural measurements without the need for subjective intervention.<sup>15</sup> This method analyzes the shape of the ONH and the peripapillary RNFL and calculates a probability of structure abnormality based on similarity to healthy or glaucomatous shapes. The GPS has been shown to perform as well as other HRT parameters that require human intervention.<sup>12</sup> The HRT software also includes a glaucoma progression analysis tool—the Topographic Change Analysis. This method calculates the probability at each point that the change from baseline exceeds the measurement variability between baseline scans.<sup>16</sup>

Several HRT parameters have been shown to precede functional abnormality. This was demonstrated in a small group of healthy subjects who developed glaucomatous visual field abnormality during the period of follow-up.<sup>17</sup> The ancillary study of the Ocular Hypertension Treatment Study showed that 55% of subjects who had ocular hypertension and later developed glaucomatous visual field abnormality had abnormal HRT results at the baseline visit, whereas the results of the visual field and expert examinations of the ONH were normal.<sup>18</sup>

## OPTICAL COHERENCE TOMOGRAPHY

Optical coherence tomography (OCT) is a noninvasive, real-time, high-resolution technology that provides optical cross-sections of the scanned region. The current commercially available iteration of the technology, spectral-domain OCT (SD-OCT), samples broad spectral information in each particular location in the tissue. By taking the Fourier transform of this information, it is able to recover tissue reflectivity information. SD-OCT uses a spectrometer and a charge-coupled-device camera to separate and detect the spectrally resolved signal. Several commercial devices of this technology are available, all using a near infrared super-luminescent diode (SLD) light source (center wavelength: 840 nm). Scanning speed ranges between the devices from 25 000 to 70 000 axial-scans per second, axial resolution of 5–6  $\mu\text{m}$ , transverse resolution of approximately 20  $\mu\text{m}$  and scan depth of up to 2.4 mm. Scanning duration depends on the scanning protocol and ranges from approximately 1 second to greater than 1 minute. Some of the devices incorporate an eye motion tracking system to reduce motion artifacts and averaging of repetitive images to reduce inherent noise level and improve image quality.

Various scanning patterns are offered by the available devices, with the most common scanning pattern for the ONH being a raster scan, which is composed of rapid succession of parallel frames. Other scanning patterns include a spoke pattern configuration of equally spaced radial scans centered on the ONH or a combination of radial and concentric circles. Many of the devices provide three-dimensional reconstructions of the scanned area (Fig. 10.7.3). (Video 10.7.1.)

Quantitative analysis of the ONH is offered without the need of delineating the ONH margin in most devices. The cup is defined by a plane parallel to the plane connecting the disc margins with a fixed offset that differs among the devices. The parameters provided vary among the devices and commonly include the disc area, cup and neuroretinal rim areas and their ratio, minimal rim width (minimal distance between Bruch's membrane opening and optic nerve head surface)<sup>19</sup> and cup volume (Fig. 10.7.4). Some of the devices include a normative data set that allows comparison and highlights measurements deviating from the normal range.<sup>20,21</sup> OCT measurements are highly reproducible<sup>22,23</sup> and have been shown to provide good discrimination ability between healthy and glaucomatous eyes.<sup>24,25</sup> RNFL thickness is the most commonly used OCT parameter to evaluate glaucoma. RNFL thickness parameters used are RNFL global average, quadrants and clock-hour sectors.<sup>25,26</sup> ONH parameters were shown to be strongly associated with visual field findings, similar to the performance of RNFL measurements<sup>24,27</sup> (see Fig. 10.7.4). SD-OCT also allows for acquisition of enhanced depth images (EDIs) of the ONH, enabling deeper structures, such as the lamina cribrosa, to be visualized (Fig. 10.7.5). An association between lamina morphology and visual field glaucomatous damage has been reported,<sup>28</sup> but in the absence of quantifiable information from the lamina cribrosa in this iteration of OCT, the clinical utility of this scan has yet to be determined.

Several commercial devices offer automated analysis for detection of glaucomatous structural progression. This analysis predominantly uses RNFL measurements, with some devices offering similar tools with ONH measurements. ONH analysis is based on a trend analysis where the rate of change is estimated over the course of follow-up (Fig. 10.7.6). Some

**Fig. 10.7.3** Three-dimensional reconstruction of the optic nerve region of a glaucomatous eye. Indentation of the temporal inferior neuroretinal rim is marked by the red arrow. Retinal nerve fiber layer wedge defect boundaries are marked with white arrows.

devices providing progression report, which combines the progression analysis of OCT parameters with visual field results to allow the assessment of corresponding structural and functional findings.<sup>29</sup>

OCT technology is rapidly evolving with new tools and biomarkers frequently presented. Swept-Source OCT (SS-OCT) is a new iteration of the technology that is becoming available commercially. SS-OCT uses a short cavity swept laser (center wavelength: 1050 nm) with a tunable wavelength of operation. Scanning speeds can reach over 400 000 per second with an axial resolution of 5  $\mu\text{m}$ .<sup>30</sup> The deeper penetration of the SS-OCT signal and the reduced depth dependent signal drop-off observed with other iterations of OCT, enables SS-OCT to evaluate deeper ocular structures, such as the choroid and the lamina cribrosa.

OCT angiography (OCTA) is a recent analysis tool that is increasingly incorporated in the clinical ophthalmological practice.<sup>31</sup> This system allows for detailed visualization of superficial and deep vascular network noninvasively and without the need for dye injection. The utility of this system in glaucoma management is currently being investigated.

Adaptive optics (AO) systems, which correct monochromatic aberrations, normally occurring in the eye, using wavefront sensing and deformable mirrors, are improving the transverse resolution. Research systems of AO coupled with scanning laser ophthalmoscopy or with OCT have been shown to substantially improve image quality and were mostly tested in the context of retinal disease. For ONH analysis, AO systems are capable of improving visualization of the lamina cribrosa microstructures, such as the pores and beams, as well as the retinal fiber bundles<sup>32,33</sup> (Fig. 10.7.7).

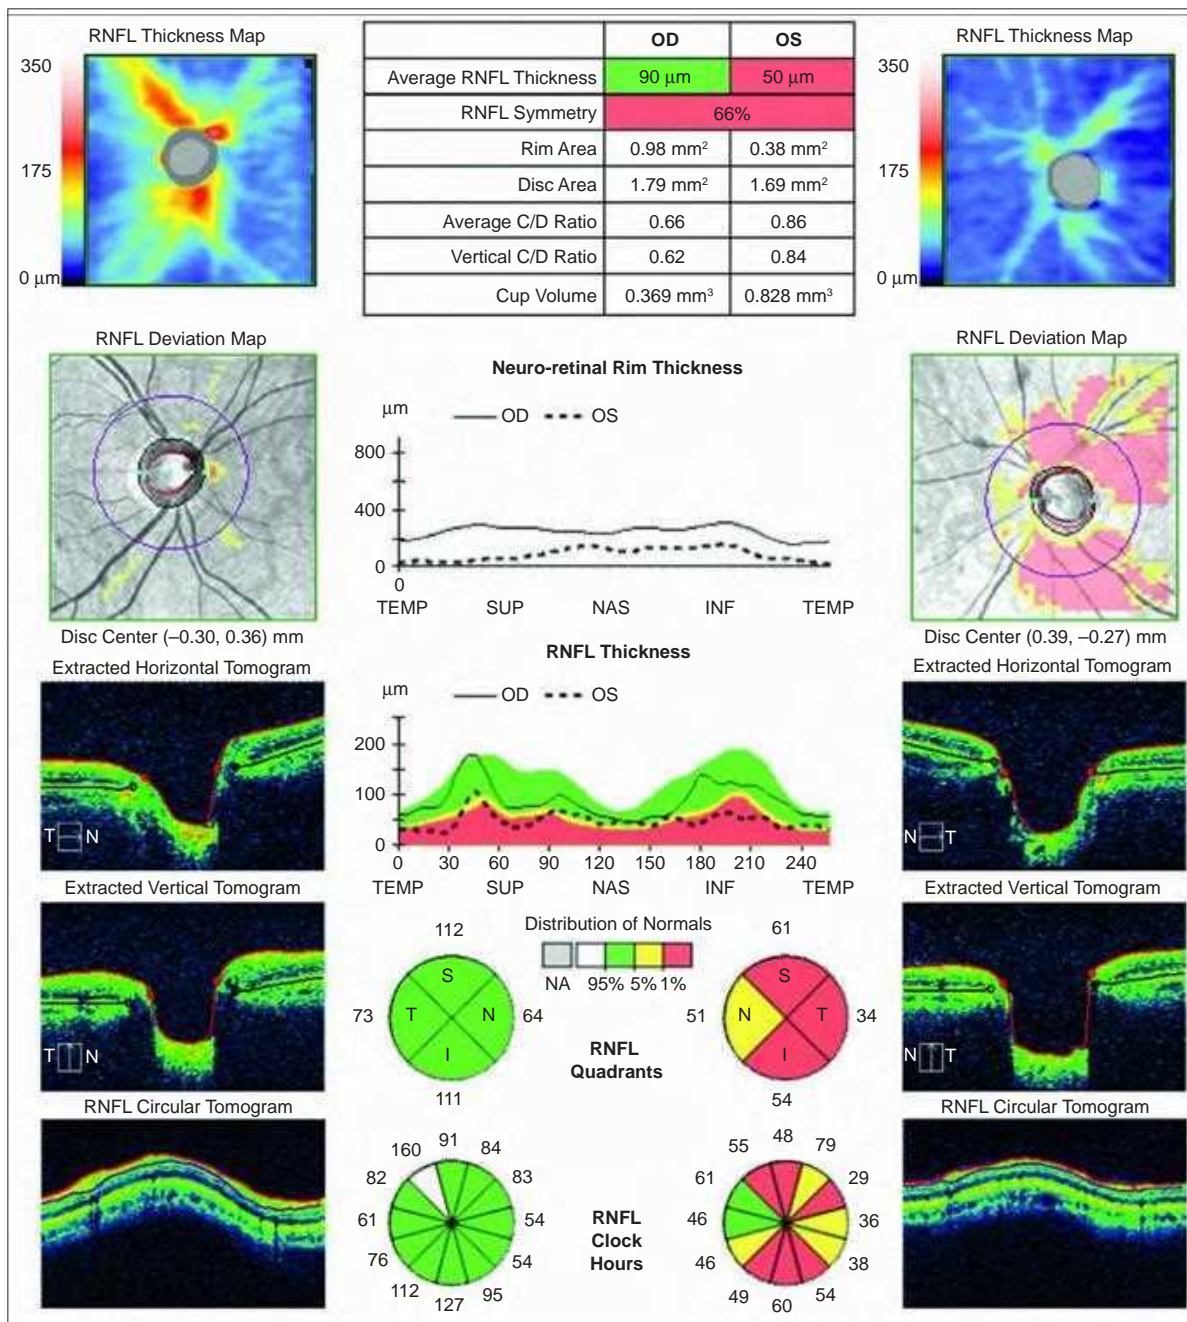

Other novel OCT systems for ONH examination undergoing research include polarization-sensitive OCT, which generates images with tissue-specific contrast based on properties that alter polarization state; and visible-light OCT, which uses wideband light source enabling high-resolution images, in vivo oximetry and spectrometry.<sup>34,35</sup>

## CONCLUSIONS

The ONH has been the cornerstone of clinical glaucoma diagnosis for a very long time. The ability to obtain detailed visualization and quantification of ONH structures through the use of ophthalmic imaging further strengthens its role in glaucoma diagnosis and progression detection.

See clip:  
10.7.1

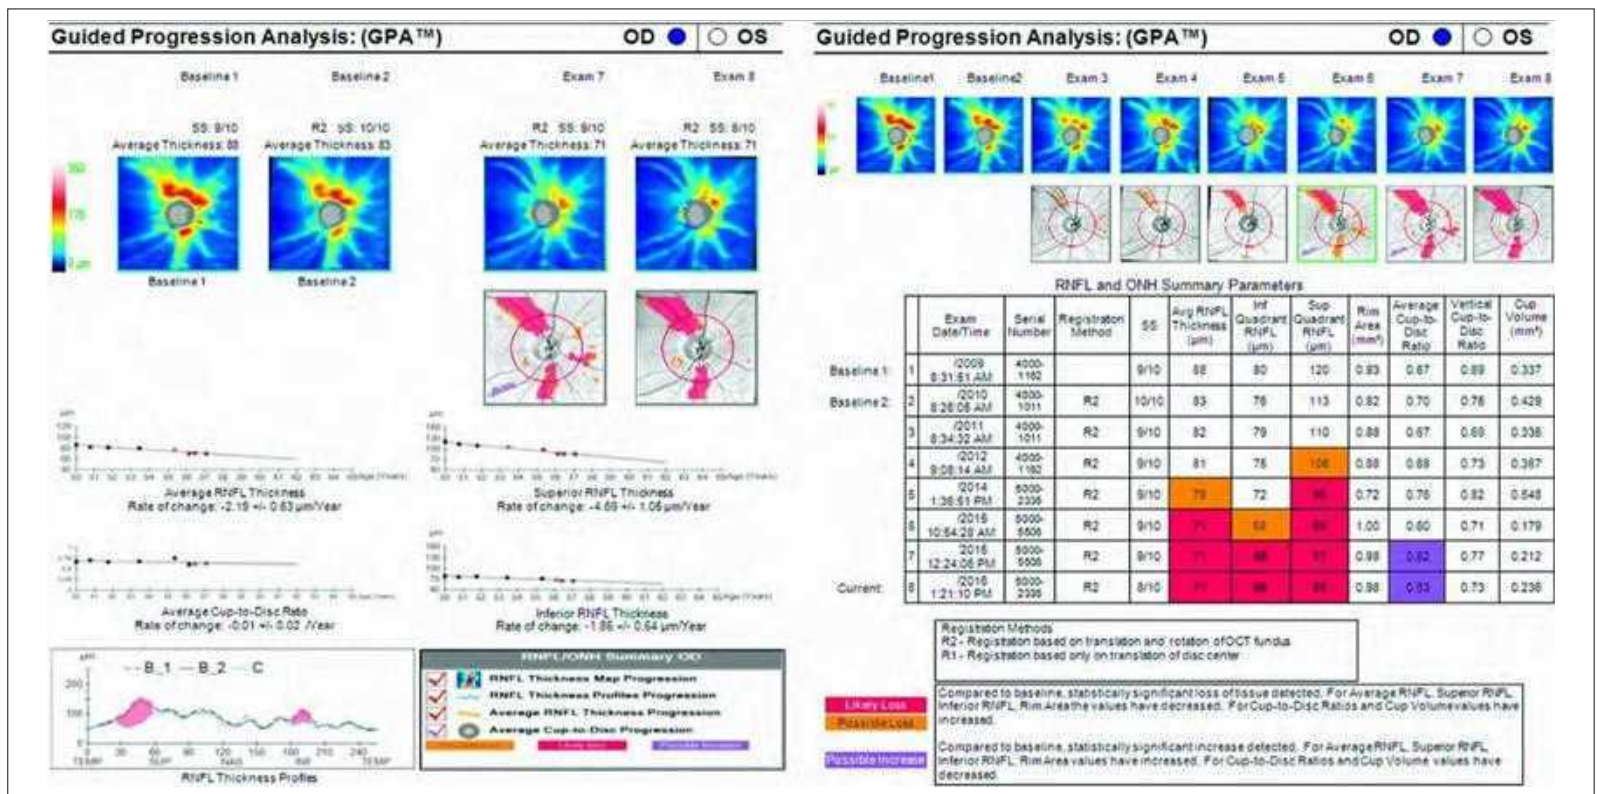

**Fig. 10.7.4** Optical coherence tomography report of the optic nerve head scan of healthy (right eye) and glaucomatous (left eye) eyes. Color-coded retinal nerve fiber layer thickness map (top) shows in the healthy eye (left) a central optic nerve head cup (light gray area) with typical thickening of the retinal nerve fiber layer (RNFL) adjacent to the optic nerve head poles (red and yellow areas). Cross-sections through the optic nerve head and surrounding circle appear at the bottom of the column. The en face image of the scanned region with the delineation of the disc and cup margins and the circumpapillary scan location is presented at the center of the left column. The glaucomatous eye (right) shows markedly enlarged cupping (top right) with nearly complete obliteration of the normally thicker RNFL superiorly and inferiorly. The RNFL damage is highlighted by the red and yellow clusters in the RNFL Deviation Map (center right). Quantitative measurements of the optic nerve head structures appear at the top of the middle column with the Average RNFL Thickness parameter within normal range for the right eye (green background) and outside normal range for the left eye (red background). RNFL symmetry between the eyes was also marked as outside normal range. RNFL thickness measurements for quadrants and clock-hours appear at the bottom of the center column, with their corresponding comparison with normative data ranges. Thickness profiles for both eyes along the optic nerve head margin (neuroretinal rim thickness) and surrounding it appear at the center of the center column.

**Fig. 10.7.5** Enhanced depth imaging B-scan with spectral domain optical coherence tomography at the location marked by the green line. (A) Vertical B-scan of an eye without glaucoma. (B) Horizontal scan of an eye with glaucomatous optic neuropathy. Structures deep within the optic nerve head, such as the lamina cribrosa (bright white area within the optic nerve head) can be detected by using this scanning method.

**Fig. 10.7.6** Optical coherence tomography glaucoma progression analysis (GPA) of the optic nerve head report of the right eye. The left page shows the two baselines used for determining the analysis of events of progression (probably loss or likely loss) and determining the rate of change of the average, superior, and inferior RNFL and the average cup-to-disc-ratio. The deviation maps of the baselines and last two visits are shown as well as a summary of the events (bottom right of the page). The second page (right) of the GPA report shows the deviation map of every visit selected and its change and a table summarizing the RNFL and ONH parameters at every visit. If there is significant change the value is flagged with yellow (possible loss) or red (likely loss).

**Fig. 10.7.7** En face view of the lamina cribrosa using adaptive optics scanning line ophthalmoscopy technology. The microstructures of the lamina cribrosa such as pores and beams can be appreciated and measured using this advance of the technology.

# Optic Nerve Blood Flow Measurement

## 10.8

Josh C. Gross, Alon Harris, Andrew Koustenis, Brent Siesky

**Definition:** Methods of assessing optic nerve blood flow in health and disease.

### Key Features

- Optic nerve anatomy.
- Optic nerve physiology.
- Clinical studies on optic nerve blood flow.
- Systemic vascular diseases and glaucoma.

### Associated Features

- Technologies for imaging optic nerve blood flow.
- Ocular blood flow and visual function.
- Pharmacology.

## INTRODUCTION

A substantial number of patients with glaucoma (perhaps up to 30%) have low/normal intraocular pressure (IOP) at the time of initial diagnosis, and the lowering of IOP does not always prevent or arrest the disease. This indicates that risk factors other than IOP alone contribute to the pathogenesis of optic nerve (ON) damage, especially in certain demographic groups. Ischemia contributing to the loss of ON axons, a concept recognized for more than 100 years, is among the foremost non-IOP risk factor with preliminary supporting data. Over the past several decades, it has become increasingly clear that vascular compromise plays a significant role in some individuals with glaucoma. Some clinical features that suggest an underlying vascular problem include localized rim notching or focal ischemic glaucoma (Fig. 10.8.1), peripapillary vasoconstriction (Fig. 10.8.2), optic disc hemorrhage, senile sclerotic optic discs with peripapillary choroidal sclerosis, and decreased ocular perfusion pressure.<sup>1,2</sup>

The precise role that ON blood flow plays in the loss of axons in glaucoma is not clear. Pallor and gross visual field loss but little cupping of

the optic disc can be seen after an acute cessation of flow in a short posterior ciliary artery (PCA) in giant cell arteritis. Furthermore, focal ischemia (which presumably arises from infarction of a small ciliary vessel in the prelaminar region) produces localized disc cupping and pallor, and a corresponding, well-defined (frequently small) visual field defect. However, to date, well-established large clinical data demonstrating specific vascular contributions in glaucoma pathology, especially vascular tissues associated with the ON, are lacking.

## APPLIED ANATOMY

The ophthalmic artery (OA) is the first branch of the internal carotid artery and gives off 2–4 posterior ciliary arteries (PCAs), which divide into 10–20 short PCAs that pierce the sclera and enter the globe around the ON. The number and route of short PCAs are variable in this region, but in general, they supply the posterior choroid and anterior ON either directly or indirectly via the arterial circle of Zinn–Haller, which, when present, is formed by the anastomosis of the medial and lateral short PCAs and circumscribes the anterior ON within the sclera.<sup>3–5</sup> The central retinal artery (CRA) enters the ON about 8–12 mm behind the globe and passes along the central axis of the nerve giving off few, if any, branches to the neural tissue. Venous drainage of the anterior ON is through the central retinal vein and into the superior ophthalmic vein.

The anterior optic nerve head (ONH) (prelaminar, laminar, and postlaminar neural tissues) is supplied by branches from the short PCAs, and the nerve fiber layer of the superficial retina receives arteriolar branches from the CRA. The capillaries of the anterior CRA (retinal and ciliary) and the ONH have tight junctions, are not fenestrated, and form a rich anastomotic plexus.<sup>6</sup> Histological examination of glaucomatous optic nerves have demonstrated a reduction in the number of capillaries consistent with the degree of neural loss, and recent optical coherence tomography angiography (OCTA) performed in patients with glaucoma has shown peripapillary capillary loss corresponding with visual field defects.<sup>7</sup>

The peripapillary choroidal circulation may contribute occasional small arterioles to the perfusion of the prelaminar and laminar ONH,<sup>6</sup> although watershed zones in the region of the ON that arise from the presence of the various interindividual segmental distributions of the various PCAs and the short PCAs may be a factor in the development of ON ischemia.<sup>8</sup>

**Fig. 10.8.1 Focal Ischemic Optic Disc Appearance (Left Eye).** Localized loss of the superotemporal neuroretinal rim in a 54-year-old woman, who has migraine and Raynaud's phenomenon.

**Fig. 10.8.2 Peripapillary Vasoconstriction in Glaucoma (Right Eye).** Marked narrowing of a branch of the inferotemporal retinal artery (at the 6 o'clock position) as it crosses the optic disc boundary adjacent to the inferior temporal vein.

Therefore, watershed zones are dependent on an individual’s anatomy, but most commonly pass through the temporal optic disc and peripapillary choroid.<sup>8</sup>

PHYSIOLOGY

Blood flow in the anterior ON relies on such factors as ocular perfusion pressure (OPP) (mean arterial blood pressure minus IOP), resistance to flow as determined by the vascular caliber in the arterioles and capillaries, and, more recently, the concept of translaminal pressure difference (IOP minus retrolaminar tissue pressure).<sup>9</sup> Vascular caliber is influenced by local mechanical, metabolic, and endothelial factors. The ability to keep local tissue flow and metabolic demand constant throughout changes in the local environment is called *autoregulation*.<sup>9</sup> Moderate changes in IOP, systemic blood pressure, and changing oxygen (O<sub>2</sub>) and carbon dioxide (CO<sub>2</sub>) conditions have little effect on anterior ON blood flow. However, if autoregulation is impaired, changes in OPP and intracranial pressure may reduce ON perfusion. In fact, patients with normal-pressure glaucoma and primary open-angle glaucoma have been found to have impaired ON and retinal autoregulation. Large population-based studies have shown that decreased OPP is a risk factor for the prevalence, incidence, and progression of glaucoma.<sup>2</sup> The difficulty in imaging specific ocular tissues currently limits our ability to connect all of these pieces of the vascular puzzle; however, advances in mathematical modeling are helping to illuminate the balance between ocular pressures and autoregulation to determine their role in ocular blood flow.<sup>10</sup>

Vascular responses in the ONH are complex and include mechanical, metabolic, and neurovascular influences. Neurovascular coupling, where active neurons directly or indirectly influence blood vessels to increase local blood flow, is mediated by several compounds including nitric oxide, adenosine, and O<sub>2</sub>.<sup>9</sup> Substances produced in response to mechanical forces play a major role in the control of ocular blood flow and include the vasodilators nitric oxide and prostacyclin, and vasoconstrictors, such as angiotensin and the endothelins. Cells that produce these substances have been identified in the choroid, retina, and ON. Repeated endothelin-1 injections into the perineural space of the ON produced chronic ischemia and excavation of the optic disc in animal studies.<sup>11</sup> Additionally, experiments modulating the activity of these substances produced changes in human ONH blood flow,<sup>9</sup> and patients with open-angle or normal-pressure glaucoma show significantly increased endothelin-1 plasma levels.<sup>12</sup> Although autonomic alpha- and beta-receptors have been identified in the ONH, they have not proven to have any functional properties.

EXPERIMENTAL INVESTIGATIONS

Blood flow in the ONH has been quantified in animal work using radiolabeled microsphere and iodoantipyrine methods, which show high flow in the prelaminar and laminar regions.<sup>13,14</sup> In the retina and ON, blood flow is

coupled closely with glucose consumption, as measured by the deoxyglucose uptake technique. In monkeys, IOP that is higher than systolic blood pressure results in complete cessation of blood flow in the prelaminar tissue, and monkey glaucoma models show increased ONH blood flow in the early stages of disease, followed by a linear decrease that strongly correlates with decreased RNFL thickness.<sup>15</sup> Theoretical mathematical models using experimental and clinical data demonstrate that loss of viscoelasticity in the lamina cribrosa caused by disease may lead to increased risk of ONH hemodynamic changes.<sup>16</sup>

CLINICAL STUDIES

Advances in measurement techniques of ocular blood flow have increased the fundamental knowledge of optic nerve perfusion and helped characterize its role in glaucoma. The anatomical vascular regions of particular interest in glaucoma include retrobulbar vessels, the capillary plexus of the superficial retinal fiber layer, pre- and intralaminar ONH, and the peripapillary choroid. It is important to acknowledge that currently no single examination technique can assess all relevant vascular beds involved in glaucoma.

Imaging of ocular and ONH blood flow has historically presented many challenges, and therefore, many modalities focus on areas accessible by laser, ultrasound, or other principles to assess some measure of ocular vascularity as shown in Table 10.8.1. Fluorescein angiography (FA) and indocyanine green angiography (ICGA) allow for qualitative study of the retinal, choroidal, and optic disc circulations, and abnormalities have been described in patients with glaucoma.<sup>17</sup> Because of poor image acquisition of the radial peripapillary capillary plexus, this technique is not commonly used.<sup>18</sup> Color Doppler imaging (CDI) using color-coded ultrasound Doppler has been utilized to measure the retrobulbar circulation with good results, and studies have found that reductions in velocities and increases in resistivity occur in all vascular beds in both high-pressure and normal-pressure open-angle glaucoma.<sup>19,20</sup> However, CDI does not have the capability to measure absolute volume flow and requires a skilled examiner. Laser Doppler flowmeter, which uses an infrared laser to analyze erythrocyte movement in the anterior ONH and peripapillary retina,<sup>21</sup> has shown diminished blood flow velocities in and around the ONH in patients with glaucoma,<sup>22</sup> and recently, strong correlations between retinal blood flow and structural changes were found in patients of African descent.<sup>23</sup> Nevertheless, there are some limitations, such as lengthy data analysis, arbitrary units of blood flow, and discontinued production. Doppler optical coherence tomography (OCT) incorporates the concepts of OCT with the ability to measure total retinal blood flow in absolute units (μL/min), and studies in patients with glaucoma have shown reduced total retinal blood flow associated with disease progression and visual field loss.<sup>24</sup> However, although absolute blood flow measurements are achieved, this modality finds limitations in measuring capillary flow in the retina and ONH and currently lacks robust longitudinal data.

TABLE 10.8.1 Comparisons of Ocular Vascular Imaging Modalities

Modality	Principle of Operation	Advantages	Disadvantages	Comments
Split-Spectrum Amplitude-Decorrelation Angiography (SSADA OCTA)	• Utilizes the reflected amplitude of an infrared laser to find the decorrelation between consecutive B scans	• Reduction of artifacts from saccadic eye movements • High signal-to-noise ratio and vessel continuity on imaging • Vessel quantification in terms of density and flow index	• Slightly compromised resolution (18 μm, compared to 5 μm without SSADA) • Difficulty imaging deeper ONH capillaries due to emergence of retinal vessels	• A high signal-to-noise ratio for imaging is achieved through bandwidth segmentation
Doppler OCT (Fourier Domain)	• Utilizes the Doppler shift to calculate velocity based on the incident light angle	• Blood flow velocity can be obtained in larger vessels	• Blood flow in small vessels is hard to measure • Detection depends on the incidence angle of the laser beam	• Blood flow velocity is obtained
Optical Microangiography (OMAG) OCT	• Utilizes a Hilbert transformation to assess scattering light reflections as either static or in motion	• Highly sensitive capillary images • Can detect blood flow as slow as 4 μm/s	• Artifacts may occur from bulk motion	• Sensitive to bulk tissue/fluid motion
Color Doppler Imaging	• Utilizes the Doppler shift principle and reflected sound waves to assess blood flow velocities	• Vessel selective, reproducible, universal units of measure • Resistive indices calculated from velocities	• Measures blood velocity, not volumetric flow	• Widely utilized, strong pilot data shows relationship of parameters to POAG outcomes
Laser Doppler Flowmetry	• Calculates temporal laser speckle fluctuations reflecting from blood cells	• Resolution to 10 μm	• Sensitive to illumination changes • Wide variation in modalities	• Useful for anterior ONH and peripapillary retina
Retinal Oximetry	• Utilizes reflected light in retinal vessels to determine the ratio of optical densities of oxyhemoglobin and deoxyhemoglobin	• Noninvasive direct measurement of retinal oxygenation	• Need for standardization • Lack of longitudinal studies	• May indicate metabolic status

**Fig. 10.8.3 Optical Coherence Tomography Angiography (OCTA) Images With Corresponding Visual Fields.** Correlation between vessel densities measured with OCTA and visual field results, in both healthy controls and patients with glaucoma. Patients with glaucoma of several degrees have progressive peripapillary vessel deficits that correspond to greater relative visual field loss. This demonstrates a relationship between structural changes and functional changes. (Used with permission from Yarmohammadi A, Zangwill LM, Diniz-Filho A, et al. Relationship between optical coherence tomography angiography vessel density and severity of visual field loss in glaucoma. *Ophthalmology* 2016 Dec;123(12):2498–508.)

## OPTICAL COHERENCE TOMOGRAPHY ANGIOGRAPHY

OCTA is a novel and noninvasive imaging modality that builds on existing OCT technology and offers the promise of highly specialized outcomes of ON vascularity. OCTA utilizes the differences in amplitude between subsequent beams of reflected infrared light to compute the quantity of blood flow (in dimensionless units), providing vessel density in the retina and optic nerve. These calculations are used to generate high-resolution images as fine as 18  $\mu\text{m}$  and provide simultaneous structural and vascular assessments.<sup>25</sup> Currently, two algorithms are being commercially utilized: split-spectrum amplitude-decorrelation angiography and optical microangiography OCT. OCTA has been utilized to investigate blood flow in segmented layers of the peripapillary retina, and studies have suggested that OCTA may be able to segment the optic disc vasculature, including deep into the lamina cribrosa. A cross-sectional study utilizing OCTA demonstrated a correlation between decreased peripapillary vessel density and corresponding visual field deficits,<sup>7</sup> as demonstrated in Fig. 10.8.3. Additional cross-sectional studies have shown the correlation of visual field deficits to be stronger with vessel density deficits than with retinal nerve fiber layer thinning in patients with glaucoma.<sup>26</sup> Studies have suggested an association between the radial peripapillary capillary plexus and RNFL thickness and visual function.<sup>27,28</sup> Huang et al. also demonstrated the depth resolved impact of glaucoma on macular vascular density, showing that the superficial vascular complex is affected, whereas the intermediate and deep vascular complexes are not.<sup>29</sup>

Although these findings are interesting and reveal that OCTA can differentiate between healthy subjects and those with glaucoma of various degrees of severity, there is a lack of OCTA-based longitudinal studies in glaucoma populations. Furthermore, currently, visualization of the deep optic disc with vasculature OCTA is poor because of shadow interference from the emerging central retinal vessels and their branches,<sup>30</sup> and its inability to assess microvascular leakage in the retina.<sup>31</sup> Currently, OCTA does not have the capability to provide comprehensive assessment of all relevant vascular beds in glaucoma, and apparent reductions in ON vascularity may only represent a consequence of ischemic insult in downstream vascular beds.

## RETINAL OXIMETRY

All but one of the methodologies listed in Table 10.8.1 measure ocular blood flow parameters, which may serve only as a surrogate assessment of tissue metabolic status. Retinal oximetry provides an assessment of ocular

**Fig. 10.8.4 Retinal Oximetry.** Color overlay of oxygen saturation in the retinal vessels.

tissue metabolic status by measuring light absorption in the retinal vessels and by calculating oxygen saturation and is a step toward understanding the true impact of ischemia on the retinal photoreceptor ganglion cells. Retinal oximetry is a highly reproducible technique,<sup>32</sup> that requires the modification of a fundus camera or similar device and the application of algorithms to record oxygen levels within arteries and veins, the difference of which is informative about tissue oxygenation and metabolism (Fig. 10.8.4). Studies of patients with glaucoma (open-angle, normal-pressure) demonstrated higher baseline mean sulfur dioxide ( $\text{SO}_2$ ) levels in retinal veins and decreased arteriovenous  $\text{SO}_2$  difference compared with the levels in healthy patients.<sup>33,34</sup> In addition, correlations between worsening rim area, RNFL thickness, and visual field defects with increased  $\text{SO}_2$  in retinal venules and decreased arteriovenous  $\text{SO}_2$  difference have been found.<sup>35</sup> As with OCTA, longitudinal studies using retinal oximetry are lacking, thereby limiting our understanding of oxygen utilization in glaucoma conversion and progression.

## Ocular Blood Flow and Visual Field Loss

The number and size of optic disc FA filling defects has been shown to increase with the severity of visual field loss in glaucoma. Using confocal scanning angiography, Melamed et al. reported a good correlation between the optic disc filling abnormalities and the visual field defect location in 75% of the 65 glaucomatous eyes studied.<sup>36</sup> Several longitudinal studies utilizing CDI now demonstrate a correlation between decreased retrobulbar blood flow velocities, higher resistivity indexes, and visual field loss, including a 4-year study with 112 patients with primary open-angle glaucoma by Moore et al., who found that lower baseline blood flow velocities predicted visual field loss.<sup>19</sup> Additionally, cross-sectional studies using OCTA have shown correlations between decreased macular and peripapillary capillary density and visual field loss in patients with glaucoma.<sup>7,27,29</sup>

## Systemic Vascular Disease and Glaucoma

It has been recognized for many years that patients with glaucoma have a higher prevalence of concomitant vascular disease compared with the rest of the population. This has been reported as particularly true in normal-pressure (tension) glaucoma. Systemic vascular disease includes the ocular vasculature, with susceptible ocular microvasculature potentially at the forefront of vascular damage. The more common systemic vascular conditions reported include cardiac disease (angina), systemic hypertension and hypotension, small vessel disease (as occurs in atherosclerosis and diabetes mellitus), and cerebrovascular disease.<sup>37,38</sup> In addition, the presence of systemic vasospastic conditions, such as Raynaud's phenomenon and migraine, are relatively common in normal-pressure glaucoma. Studies show that spontaneous and/or medically induced significant nocturnal systemic hypotension ("dippers"), especially deficits of at least 10 mm Hg compared with daytime blood pressure, predicted visual field deficits and subsequent glaucoma progression.<sup>39</sup> Increased erythrocyte aggregation and decreased erythrocyte elongation index (deformability) have been reported in patients with open-angle glaucoma, the latter of which has been shown to be significantly correlated with RNFL thickness.<sup>40</sup>

Furthermore, stronger correlations in blood flow abnormalities with glaucomatous structural damage in patients of African descent compared with those of European descent suggests possible complexity of vascular etiology across ethnicities.<sup>23,41</sup>

The concept of vasospasm has often been described in the glaucoma literature, particularly for normal-pressure open-angle glaucoma.<sup>38</sup> An abnormal vascular endothelial response (with normal anatomy) to common everyday stimuli, such as cold, stress, mechanical force, and anxiety, is implicated. Many patients exhibit a Raynaud's phenomenon-like peripheral circulation, with reduced blood flow to the fingers after immersion of the hand in cold water. This is supported by abnormal blood flow regulation, specifically impaired vasodilation in patients with normal-pressure glaucoma,<sup>42</sup> as demonstrated by impaired retinal vein vasodilation and increased retinal artery constriction.<sup>43</sup> Thickening of the intima and media of the carotid vessels in subjects with normal-pressure glaucoma has also been shown.<sup>44</sup> Migraine and silent myocardial ischemia appear to be more prevalent, and elevated systemic levels of endothelin-1 have been reported in normal-pressure glaucoma. A possible explanation for endothelin -1 contribution to ONH ischemia may be the presence of fenestrated capillaries at the prelaminar ONH, which allow for the passage of endothelin -1 and subsequent vasoconstriction of ONH vasculature.<sup>44</sup>

Therefore, for each individual patient with glaucoma, it is important that care providers review an accurate history of systemic diseases, particularly cardiovascular problems, as well as that of all systemic medications taken. Many cardiovascular drugs have potential effects within the eye, including systemic beta-blockers and calcium channel blockers (which have an ocular hypotensive effect). Obtaining accurate systemic and medication histories is important at the time of diagnosis, and it is essential that this information is regularly updated.

## PHARMACOLOGY

When reduced ocular and ON blood flows contribute significantly to the pathogenesis of axonal loss, modification of blood flow might provide protection from ischemia-induced neuronal damage; however, currently there are no treatments for vascular improvement in glaucoma. Topical carbonic anhydrase inhibitors in combination with beta-blockers increase retrobulbar, choroidal, and retinal blood flows in patients with high-pressure and normal-pressure glaucoma.<sup>45</sup> The use of calcium channel blockers for systemic hypertension may be useful in the treatment of normal-pressure glaucoma,<sup>46</sup> although some studies have shown evidence that these drugs may promote glaucoma progression.<sup>47</sup> In some patients, improvement in ocular blood flow and contrast sensitivity is seen with calcium-channel blockers or inhaled CO<sub>2</sub> in short-term investigations. Additionally, patients with normal-pressure glaucoma experienced a smaller deterioration rate of visual field sensitivity after 2 years of oral brovincamine, a relatively

selective cerebral vasodilator with weak calcium antagonist action.<sup>48</sup> Medical and surgical reduction of IOP may, in some patients with glaucoma, improve ocular blood flow as well.<sup>49,50</sup>

Advances in imaging modalities and efforts to establish longitudinal data, especially in ON tissue beds, may allow for improved and individualized glaucoma management planning, resulting in better patient outcomes.

## STATEMENT OF DISCLOSURE

None of the listed authors has any competing interests with submission of this manuscript. Dr. Alon Harris would like to disclose that he receives remuneration from Stemnion, Biolight, Nano Retina, AdOM, Science-Based Health, Isarna Therapeutics, and Ono Pharmaceuticals for serving as a consultant. Dr. Harris also holds an ownership interest in AdOM, Nano Retina, and Oxymap. All relationships listed above are pursuant to Indiana University's policy on outside activities. None of the other authors listed have any financial disclosures.

**Definition:** Although there is no absolute number separating normal intraocular pressure (IOP) from abnormal IOP, ocular hypertension is a condition in which IOP is above the usual range but without any evidence of structural or functional optic nerve damage.

## Key Features

- IOP greater than 21 mm Hg without evidence of secondary causes.
- No evidence of optic neuropathy or nerve fiber layer loss.
- No visual field loss.
- Open angles on gonioscopy.

## INTRODUCTION

Intraocular pressure (IOP) is the only modifiable risk factor for primary open-angle glaucoma (POAG), and patients with ocular hypertension (OHT) are at greater risk for developing the disease. Predictive factors for the conversion of OHT to POAG can be used to guide the clinician in determining how to individualize management for patients with OHT, including the frequency of examinations and the potential benefit of early treatment.

## EPIDEMIOLOGY AND PATHOGENESIS

OHT is estimated to affect from 4.5%–9.4% of middle-aged and older adults in the United States.<sup>1</sup> The prevalence of OHT varies among different ethnic groups. The Afro-Caribbean population in the Barbados Eye Study was found to have one of the highest reported prevalence rates of OHT (12.6%).<sup>2</sup> In contrast, other studies found the prevalence of OHT was 1.1% in southern India<sup>3</sup> and 0.9% in Japan.<sup>4</sup> The prevalence rate of OHT increases substantially with age. In the Framingham Eye Study, 6.2% of white participants under age 65 years had an IOP greater than 21 mm Hg, compared with 8.7% in those over age 75 years.<sup>1</sup>

## Predictive Factors for Conversion of OHT to POAG

The Ocular Hypertension Treatment Study (OHTS) provided valuable data about progression from OHT to POAG. The predictive factors from the OHTS are discussed below.

## Central Corneal Thickness

The OHTS trial showed that baseline central corneal thickness (CCT) was a powerful predictor of the development of POAG among OHT participants.<sup>5</sup> In OHTS, eyes with a CCT of 555  $\mu$ m or less had a threefold greater risk of progression to glaucoma at 5 years compared with participants who had a CCT of greater than 588  $\mu$ m. Fig. 10.9.1 demonstrates the percentage of the observation group that developed POAG, determined on the basis of baseline IOP and CCT.<sup>5-7</sup>

## Intraocular Pressure

Higher IOP is a predictive factor of progression from OHT to POAG. The relative risk is 1.1 for each 1 mm Hg increase in baseline IOP within the range of the study.

## Age

Older participants had a greater risk of conversion to glaucoma.

## Pattern Standard Deviation

A greater baseline pattern standard deviation (PSD) on standard automated perimetry correlated with increased risk of progression from OHT to POAG.

## Optic Nerve

Even when patients with OHT had no clinically apparent glaucomatous structural damage, a larger cup-to-disc ratio was a risk factor for progression.

## Optic Disc Hemorrhage

In a multivariate analysis, the occurrence of an optic disc hemorrhage increased the risk of developing glaucoma 2.6-fold.<sup>8,9</sup>

## Other Predictive Factors

Race was found to be significant in the univariate analysis, but not in the multivariate analysis of the OHTS when cup-to-disc ratio and CCT were included. However, many studies support the finding that POAG is 3–4 times more prevalent in black versus white populations.<sup>10-12</sup> Although family history was not found to be a significant predictor for progression in the OHTS, other studies have shown it to play a key role in the susceptibility to POAG.<sup>13,14</sup> Genetic studies have not yet found risk alleles or genes with enough of an effect to warrant routine clinical testing.<sup>15</sup>

## DIAGNOSIS

Thorough medical and ocular histories must rule out any secondary causes of elevated IOP, such as corticosteroid use or trauma. A complete ophthalmic examination with the following key components is necessary:

- *Tonometry*—IOP greater than 21 mm Hg.
- *Ophthalmoscopy*—normal optic nerve with no evidence of glaucomatous cupping or nerve fiber layer (NFL) loss.
- *Standard automated perimetry*—no evidence of visual defects.
- *Pachymetry*—measurements should be performed over the central cornea in an area without pathology.
- *Gonioscopy*—open angles with no evidence of pathology.
- *OCT*—definitive longitudinal studies have not been performed to establish diagnostic thresholds for distinguishing between OHT and POAG, but there is evidence that a thin NFL correlates with high risk OHT.<sup>16-18</sup> OCT can also detect loss of macular ganglion cells.<sup>19</sup>

Other tests that may be beneficial include the following:

- Corneal hysteresis.
- Heidelberg Retina Tomography.
- GDX-scanning laser polarimetry (Laser Diagnostic Technologies, San Diego, CA).

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis for OHT includes undiagnosed POAG as well as secondary causes of OHT, such as topical or systemic corticosteroid use, angle recession, and angle-closure glaucoma.

**Fig. 10.9.1** Graph demonstrating the effect of central corneal thickness and baseline intraocular pressure on progression to glaucoma in patients with ocular hypertension. These results were derived from an analysis of pooled data from the Ocular Hypertension Treatment Study and the European Glaucoma Prevention Study. (Reproduced from data, Ocular Hypertension Treatment Study Group and European Glaucoma Prevention Study Group. Validated prediction model for the development of primary open-angle glaucoma in individuals with ocular hypertension. *Ophthalmology* 2007;114:10–19, copyright 2007, with permission from the American Academy of Ophthalmology.)

## TREATMENT

The OHTS trial provided predictive factors (CCT, PSD, age, cup-to-disc ratio, disc hemorrhage, and IOP) that should be considered when deciding whether to treat OHT and confirmed the safety and efficacy of treating OHT with topical medications. Specifically, it determined that ocular hypotensive medication reduced the rate of progression of OHT to POAG by 50% at 10 years. The absolute reduction in POAG incidence was greatest in participants in the highest tertile of baseline risk (from 42%–19%).<sup>20</sup>

Treatment of OHT can be considered in high-risk patients after taking into account patient preference, age, and health status. Patients at low risk of conversion can be followed up yearly, typically without treatment, as long as they are monitored for signs of early disease.<sup>21–23</sup> With this treatment plan, regular follow-up examinations and testing are critical. Some physicians may prefer to monitor all patients with OHT, initiating medication only after early damage is detected. It is important to involve the patient in the decision making so that an individualized treatment plan can be created.

Patients can be stratified by risk calculators derived from the OHTS and European Glaucoma Prevention Study data.<sup>24</sup> Cost-effectiveness analysis using OHTS data supports treating patients with OHT if there is at least a 2% annual risk of development of POAG.<sup>25,26</sup> Although the calculator may help guide the clinician in determining patient management, it should not supersede clinical judgment.<sup>27,28</sup>

## COURSE AND OUTCOME

The majority of patients with OHT do well over long periods of follow-up. The accepted average rate for progression from OHT to POAG is 1%–2% per year, but subgroups with higher risk do exist. In eyes with OHT that did not reach an endpoint for POAG, the rate of change of mean deviation was slow (–0.05 dB/yr), whereas eyes that converted to POAG progressed at a faster rate (–0.26 dB/yr).<sup>29</sup> Although data from the OHTS suggest that visual field change in early glaucoma is most commonly localized, a significant number of individuals will show diffuse changes that may go undetected if only pattern deviation analyses are used.<sup>29,30</sup> The earliest changes of POAG, however, were most commonly structural, highlighting the importance of clinical examination, optic disc photography, and imaging of the optic nerve and NFL.

In general, high-risk patients who are treated are likely to have good outcomes. For patients who are monitored without treatment and who progress, early detection of damage and treatment may slow further progression.

# Primary Open-Angle Glaucoma

James C. Tan, Paul L. Kaufman

# 10.10

**Definition:** Age-related optic neuropathy characterized by progressive optic nerve cupping, visual deficit, and gonioscopically open angles.

## Key Features

- Glaucomatous optic disc cupping and retinal nerve fiber loss.
- Corresponding visual field abnormality.
- Open anterior chamber angles.
- Intraocular pressure as a major and only modifiable risk factor, applicable at every pressure level but with higher pressures posing greater risk.
- Progressive, age-related condition.

## Associated Features

- Corneal thickness.
- Chronic disease.
- Visual impairment.

## DEFINITION AND CLASSIFICATION

The term *glaucoma* describes a progressive optic neuropathy with characteristic optic disc cupping and corresponding visual deficit. The condition has as its basis gradual loss of retinal ganglion cells (Fig. 10.10.1) and axons traversing the retina and the optic nerve (Fig. 10.10.2) to the brain. Intraocular pressure (IOP) is a major modifiable risk factor. Glaucoma is progressive; left unchecked, it may cause blindness.

Glaucoma is classified as *primary* if elevated IOP is of unknown etiology and *secondary* where an etiological factor is identifiable. Conventionally, the term *primary open-angle glaucoma* (POAG) has been applied to adult primary chronic glaucoma, in which the anterior chamber drainage angle is open and IOP elevated for no apparent reason. Overall prevalence of POAG in the United States is about 1%, with this varying ethnically,

wherein the rates among African American and Hispanic Americans are reported to exceed 4%.<sup>1,3</sup> These rates increase with increasing age in all ethnicities.

Two other entities are closely considered with POAG. People with ocular hypertension have open angles and elevated IOP (>21 mm Hg) that has apparently not caused nerve damage. They are at heightened risk of developing glaucoma. People with so-called normal-tension glaucoma (NTG) have primary chronic glaucoma and open anterior chamber drainage angles but IOP within normal statistical limits (<22 mm Hg). NTG is now classified as part of the POAG spectrum. Neither ocular hypertension nor NTG is rare<sup>4,5</sup>; ocular hypertension is more prevalent than POAG, whereas at least 30% of those with POAG have NTG.

This chapter will discuss the risk factors for POAG, the nature of progressive visual loss in the disease, and the broad principles of diagnosis and treatment.

## INTRAOCULAR PRESSURE, RISK FACTORS, AND ASPECTS OF MOLECULAR PATHOGENESIS

Many epidemiological, clinical, histopathological, and experimental studies support the role of IOP in glaucoma pathogenesis.<sup>6,7</sup> However, what constitutes glaucoma-inducing IOP is not always clear in patients. The traditional cutoff for “normal” IOP of 21 mm Hg has its source in a German population survey in the 1950s.<sup>8</sup> This analysis assumed that the distribution of IOP is normal, but it is, in fact, skewed toward higher IOP.<sup>6</sup> The right-skew increases with age and varies with race. This statistical quirk means that the proportion of people with IOP exceeding 21 mm Hg and having glaucoma is less than initially predicted, and many will be diagnosed with ocular hypertension. We now realize that glaucoma-related pathological IOP has a continuous distribution and does not obey a strict cutoff.

Eyes with ocular hypertension are at increased risk of POAG. The risk of developing POAG is up to six times higher in those with ocular hypertension than in those without any risk factors for glaucoma.<sup>9</sup> The risk of developing POAG in ocular hypertension in the Ocular Hypertension

**Fig. 10.10.2 Histopathological Correlation of Glaucomatous Optic Disc Cupping.**

(A) Normal human optic nerve with a small cup. Axons of the thick retinal nerve fiber layer turn posteriorly to form the neuroretinal rim of the optic disc. The lamina cribrosa of the anterior optic nerve is transversely orientated in continuity with flanking sclera. (B) Glaucomatous optic nerve with a markedly thinned retinal nerve fiber layer and neuroretinal rim, large cup, and posteriorly bowed lamina cribrosa. (Photos courtesy Dr. Morton E. Smith.)

Treatment Study was 9.5% over 5 years.<sup>10</sup> In a standard clinic setting this may be observed as 1%–2% per year<sup>11,12</sup> or about 10% per decade.<sup>13</sup> This risk rises with IOP, increasing significantly at pressures over 24 mm Hg, and especially over 30 mm Hg.<sup>6,10,11,14,15</sup> POAG risk is further influenced by other factors, such as age, ethnicity, and central corneal thickness (see later).

The entity NTG is prevalent in east Asia, comprising over 80% of open-angle glaucoma.<sup>16,17</sup> The matching prevalence in Western countries is 30%–55%, based on isolated IOP readings in population studies,<sup>2,4,18</sup> although it is reported to be as high as 75%–82% in Hispanic Americans in Arizona,<sup>19</sup> Los Angeles Latinos,<sup>1</sup> and Australian Blue Mountains Caucasians.<sup>5</sup> Underdiagnosis of glaucoma<sup>1,4,5</sup> is not surprising given the traditional focus on IOP for glaucoma case-finding. Although IOP may not seem that high in NTG, it is still too high for these eyes,<sup>16</sup> and disease progression may be slowed by reducing IOP.<sup>20,21</sup>

Higher-than-normal IOP fluctuation occurs in POAG (including NTG) and may be evident as IOP peaks at certain times of day or with certain postures.<sup>22–25</sup> A further consideration is that the natural history of IOP in any individual is typically unknown; that is, in an eye with POAG we know little of the past course IOP has taken to become elevated, and we cannot predict its future course. We also do not know if IOP in some NTG persons has risen from an even lower baseline over time. A rise of IOP in POAG is not measureable over 6 years, but it is in pseudo-exfoliation glaucoma,<sup>22</sup> which is not surprising given the more pronounced IOP elevation and disease progression of the latter.<sup>22,26,27</sup> It does suggest, however, that a presumed IOP rise in POAG occurs gradually, perhaps over a decade or more.

Pathological IOP elevation in POAG is attributed to increased resistance to aqueous humor outflow.<sup>28</sup> In POAG, aberrant plaque-like accumulations of fine fibrils associate with elastic microfibrils of the trabecular meshwork,<sup>29–32</sup> a contractile and richly elastic drainage tissue that is an important site of aqueous outflow resistance. Nevertheless, only modest IOP lowering is yielded by surgically bypassing the trabecular meshwork,<sup>33</sup> suggesting that pathogenic roles of other drainage sites such as the intrascleral channels and uveoscleral pathway ought to be considered. Cellular and molecular mechanisms regulate these pathways and determine IOP.<sup>34</sup> An important POAG disease biomarker of still unknown origin is the aqueous level of transforming growth factor beta (TGFβ) that is consistently elevated in POAG eyes across diverse populations.<sup>35–42</sup> Elevated TGFβ causes trabecular meshwork stiffening and altered contractility that can increase outflow resistance.<sup>43</sup> New classes of pharmaceutical agents targeting trabecular contractility are presently in the development pipeline for POAG therapy.

Besides IOP, the strongest independent risk factor for developing POAG is age, with subjects aged greater than 60 years many times more likely to develop glaucoma than those in their 40s.<sup>1,3,5,11,19,44</sup> Glaucoma is more prevalent in people of Hispanic and African descent,<sup>1,3,44</sup> with the latter typically younger and having higher IOP and more advanced optic neuropathy at initial diagnosis compared with Caucasians. Their disease is also more refractory to treatment and has a worse prognosis.<sup>45</sup> IOP fluctuation itself is considered by many to be a risk factor for disease progression.<sup>23,24,46–52</sup>

Other significant risk factors are genetic predisposition and a positive family history. A further independent and important risk factor is thin

central corneas, which may be related to structural factors conferring on the optic nerve susceptibility to damage.<sup>10,53</sup> Thin central corneas may also cause IOP underestimation.<sup>10,54</sup> Myopia, diabetes, systemic hypertension, and vascular conditions, such as migraine and vasospasm, are also considered risk factors for POAG, although the evidence is more ambiguous.

Large epidemiological and randomized control studies from recent decades have yielded vital quantitative data on the link between risk factors and glaucoma.<sup>55</sup> In the future, such information may be useful for estimating the actuarial risk of glaucoma in individuals, providing an extra tool for case-finding, diagnosis, and treatment.

## DIAGNOSIS

Diagnosing POAG requires evaluation of IOP; the anterior chamber angle by gonioscopy; optic disc and related structures, such as the retinal nerve fiber and ganglion cell layer; and visual field.

IOP has a normal diurnal variation that is more exaggerated with disease.<sup>56</sup> IOP is usually measured by Goldmann applanation tonometry. In measuring IOP, clinicians should be aware of extremes of corneal thickness,<sup>57</sup> wherein IOP is overestimated in thick corneas and underestimated in thin corneas because Goldmann tonometry assumes a central corneal thickness of 550 microns. This is important to consider in individuals who have had laser refractive surgery or who carry a diagnosis of NTG or ocular hypertension.<sup>10</sup>

The optic disc is evaluated for glaucomatous cupping (Fig. 10.10.3). In practice, it can be difficult to separate normal optic discs from glaucomatous optic discs on the basis of appearance. The reason is that the range of normal disc morphology overlaps with that of glaucoma, especially with early disease.<sup>58</sup> Optic disc stereophotography and retinal nerve fiber layer observation by red-free funduscopy or photography are traditional methods for assessing structural abnormality or change, with disc photography still commonly used. Newer imaging technologies, such as optical coherence tomography, have special analytical algorithms to help identify glaucomatous damage to the retinal nerve fiber layer and ganglion cell complex.

Evidence of reproducible visual field abnormality on standard “white-on-white” perimetry is enough to corroborate the suspicion of a glaucomatous-appearing optic disc. The visual field defect should correspond to the region of perceived optic disc abnormality. Although white-on-white visual field defects may not be the earliest sign of visual deficit in glaucoma (see next section), perimetry remains essential to diagnosing glaucoma.

## NATURE OF PROGRESSIVE VISUAL LOSS

Observing visual field change over time can inform on how POAG progresses. Progression may be considered in four phases: preperimetric (occult), threshold, critical,<sup>59</sup> and compatible with blindness.

### Preperimetric Glaucoma

Initially, disease is subclinical during a prolonged occult period in which white-on-white visual fields—the standard for diagnosis—remain normal. Any decreased visual sensitivity during this time is still too subtle to be

**Fig. 10.10.3 Progressive Glaucomatous Optic Neuropathy.** (A) Glaucomatous optic disc. (B) The same optic disc 3 years later. There is increased cupping associated with localized rim thinning inferiorly.

detected by perimetry because for this to happen, sensitivity must be decreased enough to consistently remain below the age-matched normal population visual threshold of detection. Perimetric signs, if present, are nonspecific and include blind spot change, isopter shrinkage on kinetic perimetry, and increased regional variability.<sup>60-62</sup> Other parameters of visual function, such as sensitivity to contrast, color (blue-yellow perimetry), motion, and the spatial frequency doubling illusion (frequency doubling perimetry), may already be abnormal. Despite visual fields being well preserved, significant retinal ganglion cell loss, progressive disc cupping (Fig. 10.10.4) and retinal nerve fiber layer thinning may already be present.<sup>63-66</sup>

**Fig. 10.10.4 Longitudinal Scanning Laser Tomography Images of the Optic Nerve in an Eye With Ocular Hypertension.** There is progressive and widespread neuroretinal rim loss over time so that the optic cup is enlarged concentrically. (Top row) Topography images. (Second row) Color-coding indicates the neuroretinal rim (blue and green) and optic cup (red). (Third row) Image analysis indicates parts of the rim (blue-green) and corresponding cup (red) that are significantly altered over time. This pathological change affected over three-quarters of the rim circumference despite visual fields remaining normal. (From Tan JC, Hitchings RA. Approach for identifying glaucomatous optic nerve progression by scanning laser tomography. *Invest Ophthalmol Vis Sci* 2003;44:2621-6.)

## Threshold and Conversion

The term *conversion* refers to persistent visual field defects developing in previously normal visual fields. It describes the appearance of visual field abnormality over time in those suspected to have glaucoma. Normal fields “convert” when visual sensitivity in one or more regions decreases to persistently lie outside normal limits. This is often gradual, although these early visual field defects may appear transiently or abruptly because they are just at the threshold of detection.<sup>59</sup> They may disappear after treatment, only to reappear later, and it could be years before they become consistently present.

At conversion the earliest visual field defects involve small regions in the arcuate and central 30° of the visual field, and nasal steps.<sup>60-62</sup> Inferior arcuate defects are mainly nasal, but superior arcuate defects are more central and nearer fixation. Conversion does not imply a sudden appearance of glaucoma but rather that previously preperimetric disease has worsened to become detectable.

## Critical Phase

When the earliest consistent visual field defects appear, disease is no longer early as ~50% of ganglion cells and axons may already be lost.<sup>63,64,67</sup> Despite treatment many eyes may show visual deterioration. In unilateral glaucoma, there is a 26% risk of visual field abnormality developing in the fellow eye within 5 years.<sup>67</sup> Without adequate treatment the risk of vision deteriorating to cause functional impairment within a decade is significant.<sup>68,69</sup>

Scotomata frequently evolve by deepening, but enlarging arcuate defects and the appearing of new defects are also common.<sup>70</sup> Change over time usually follows a linear or curvilinear course, but it may also seem episodic and more stepwise. Bigger and denser scotomata tend to deteriorate faster.<sup>71</sup> The upper and lower visual field hemispheres show differing susceptibilities to developing abnormality, but over a decade, roughly a third of eyes with only one hemisphere affected initially will develop bi-hemispheric abnormality.<sup>59,70</sup> Because upper hemispheric involvement tends to be more central,<sup>72</sup> the visual impact of such abnormality is expected to be greater. Simultaneous bi-hemispheric involvement carries a poor prognosis; without adequate treatment, up to half these eyes will suffer absolute visual field loss over a decade.<sup>44</sup>

## Blindness

Blindness may occur despite treatment. Studies show the following: Despite treatment, the risk over 20 years of developing unilateral and bilateral blindness is 27% and 9%, respectively<sup>73</sup>; the cumulative rate of

glaucoma blindness despite treatment is 19% over 22 years<sup>74</sup>; despite IOP being controlled below 22 mm Hg, the probability of retaining useful vision declined by 31% over 15 years, with half of visual disability attributable to glaucoma.<sup>69</sup> This high incidence of blindness is seen in both developed and developing countries.

Glaucoma affects 60–70 million people worldwide and is the leading cause of irreversible blindness.<sup>75,76</sup> It is estimated that three quarters of people with glaucoma have the open-angle variant, and of these, almost 10% are bilaterally blind.<sup>75</sup> POAG is the most prevalent form of glaucoma in the United States, where it is the leading cause of blindness in African Americans and Hispanic Americans and the third leading cause in Caucasians.<sup>75,77</sup> The prevalence of glaucoma blindness markedly increases with age. Glaucoma blindness is higher in African Americans compared with Caucasians, with African Americans going blind 10 years earlier, on average.<sup>78</sup> Sometimes severe visual impairment is already present at diagnosis. In the Olmstead County Community Study in Minnesota, 10% of subjects were at least unilaterally blind at diagnosis, and of these, 2% were bilaterally blind. The 20-year cumulative risk of glaucoma-related unilateral blindness was 26% and bilateral blindness was 9%.<sup>68</sup>

## TREATMENT AND MONITORING

IOP is the only risk factor that can be manipulated to stop or slow glaucoma progression. Rigorous IOP-lowering can help control POAG.<sup>20,21,79–84</sup> This is commonly achieved with medication, laser, surgery, or some combination thereof. Currently, it is not known how other risk factors influence the disease or how these risk factors may be altered. Patients with ocular hypertension at high risk of conversion may benefit from closer monitoring or treatment to modify risk.<sup>83</sup> Clinicians are forced initially to guess a level of IOP—known as “target pressure”—which will stop or slow further damage.<sup>82</sup> Once target pressure is achieved, the level of IOP still needs to be monitored because it may change over time, fluctuate, or not be low enough.<sup>84</sup> Isolated clinic measurements do not necessarily predict the peak and range of IOP variation that affects the likelihood of glaucoma progression. The possibility of higher IOP may be verified by checking IOP at different times of the day, although this does not fully capture nocturnal variations, and there remains a need for new technologies to monitor IOP continuously.

Treatment needs to be individualized because the IOP level needed to control disease varies widely among individuals. There is no universal formula to tell how much IOP needs to be reduced. There is need for clinical judgment, aided by reliable clinical measurements, where available. Patients with moderate or advanced disease especially with fixation-threatening visual loss (Fig. 10.10.5) may benefit from earlier surgery and more aggressive IOP lowering.<sup>85</sup> Lowering IOP, however, has limits, as determined by treatment side effects and possibility of hypotony, especially after surgery.

The real guide for long-term clinical management is not IOP but the course taken by the optic neuropathy. It is standard practice to sequentially examine the visual field and optic disc to ascertain progression. But reliably detecting progression using subjective and qualitative methods is not easy,<sup>86</sup> especially when trying to identify smaller amounts of disease-induced change. It is important to determine if perceived change from testing is real and reproducible and not caused by test variability. It is hoped that newer objective, quantitative, and potentially more reliable vision (e.g., multifocal visual evoked potential) and imaging tests (see Fig. 10.10.4) will help in this regard.

POAG is a chronic disease, and patients are more likely to comply with treatments if they understand the nature of the disease and the need for ongoing treatment and monitoring. Noncompliance with medical treatment is a significant barrier to effective control of the disease, being reported in 30%–80% of patients.<sup>87–89</sup> One reason for noncompliance is that glaucoma treatments may cause symptoms, whereas the disease may otherwise be asymptomatic. Older patients are especially susceptible to the systemic side effects of glaucoma medications (e.g., beta-blockers). It is useful to involve patients' families as supports, where possible.

Timely and effective treatment is critical to preventing visual disability resulting from POAG. It is vital that the clinician develop some estimate of the rate of progression, its likely threat to central fixation, and lifetime risk of functional visual compromise. Factors that may influence prognosis, such as race, age, or family history, ought to be taken into account, as should other issues common to chronic disease such as the coexistence of other illness, life expectancy, quality of life, and the cost and side effects of long-term treatments.

**Fig. 10.10.5** Examples of Visual Fields in Which Paracentral Field Locations Are Affected and Fixation Is Threatened or Involved. Each of five visual field pairs is enclosed within a box. (First row, left box) Scotoma in the right (R) eye extends from the blind spot affecting both superior paracentral locations. Paracentral perimetric locations are indicated by blue spots in the left eye (L) visual field, which is normal. Field damage is clearly asymmetric. (First row, right box) The right eye has developed a superior altitudinal defect with deeper defects in paracentral locations. Paracentral defects in the left eye have first developed inferiorly, which is somewhat less common. (Second row, left box) Fixation threat associated with bi-hemispheric field involvement carries a poor prognosis. (Second row, right box) The left eye has a dense superior arcuate defect with paracentral sparing that is helping compensate for paracentral loss in the right eye. It is critical to therapeutically preserve paracentral vision in the left eye. (Third row) Both eyes had residual central islands. Three of four paracentral locations were affected with fixation split as seen in the corresponding 10-2 fields.

# Normal-Tension Glaucoma

Louis R. Pasquale

# 10.11

**Definition:** A progressive excavation of optic nerve head tissue despite recorded intraocular pressures that are typically tolerated by most patients.

## Key Features

- Preponderance of untreated intraocular pressure readings that are only slightly higher compared with patients without glaucoma.
- Glaucomatous cupping with loss of prelaminar neural tissue accompanied by variable amounts of laminar displacement posteriorly and under the neuroretinal rim.
- Visual field loss patterns conforming to retinal nerve fiber layer loss.
- Open angles on gonioscopy.
- No history of eye disease with raised intraocular pressure.

## Associated Features

- Vascular endothelial cell dysfunction.
- Headache with or without features of migraine.
- Optic disc hemorrhage.

## INTRODUCTION

With the relaxation of intraocular pressure (IOP) criteria for primary open-angle glaucoma (POAG), it is now recognized that a significant percent of glaucoma cases present with IOP 21 mm Hg or less. In fact, there is considerable overlap in disease features between cases that present with IOP above and below the arbitrary IOP cutoff of 21 mm Hg. Normal tension glaucoma (NTG) is a potentially blinding disease, where the optic nerve sustains load-bearing failure in the face of measured IOPs that should be tolerable but nonetheless lead to excavation and erosion of the neuroretinal rim tissues.

## EPIDEMIOLOGY AND PATHOGENESIS

In the landmark Barbados Eye Study, 47.8% of incident open-angle glaucoma cases had a baseline IOP 21 mm Hg or less.<sup>1</sup> In analytical epidemiological studies performed in the Nurses Health Study and Health Professionals Follow-up Study, approximately 30% of incident POAG cases had known maximum IOP 21 mm Hg or less.<sup>2</sup> Interestingly, in a Korean population-based study only 38 of 10,096 subjects had IOP greater than 21 mm Hg (0.4%), and therefore almost all of the incident POAG cases could be designated as NTG by using the arbitrary definition of idiopathic optic nerve head excavation associated with known maximum IOP less than 22 mm Hg.<sup>3</sup>

A contemporary view of disease pathogenesis is that load-bearing sclera fails leading to backward bowing of the lamina cribrosa, although concomitant primary neuronal/glial cell support failure cannot be ruled out. This backward bowing produces an axonopathy that ultimately manifests clinically as cupping and characteristic visual field loss. This optic nerve head vulnerability is created by a combination of inherent connective tissue weakness, genetic factors, vascular mechanisms, autoimmune deviations, and inflammatory insults.

One genetic region that contributes to optic nerve vulnerability in NTG is *CDKN2B-AS*,<sup>4,5</sup> but exactly how gene variants in this region contribute to optic nerve degeneration is unclear. A meta-analysis of seven candidate gene association studies suggest that two common polymorphisms in *OPA1* are associated with NTG.<sup>6</sup> Haploinsufficiency in *OPA1* produces

mitochondrial dysfunction and causes a mendelian form of dominant optic atrophy.

Vascular mechanisms may involve nocturnal hypotension, vascular dysregulation, and autonomic dysfunction. Evidence for an immune deviation comes from work showing an abundance of serum paraproteins and autoantibodies in NTG versus controls.<sup>7</sup> Furthermore, the discovery of rare optineurin (*OPTN*) variants in familial POAG that includes patients with known maximum IOP less than 22 mm Hg, implicates impaired tumor necrosis factor alpha signaling in NTG.<sup>8</sup>

## OCULAR MANIFESTATIONS

No characteristic ocular features distinguish NTG from POAG that develops in association with higher IOP levels. However, NTG has some notable ocular features. The IOP may be slightly higher in the more severely affected eye, although the difference may only be 1–2 mm Hg.<sup>9,10</sup> In a study from South Korea, the preponderance of diurnal IOP measurements in untreated NTG were less than 22 mm Hg.<sup>11</sup>

Patients with NTG are more likely to exhibit optic disc hemorrhages compared with those with POAG with higher IOP.<sup>12</sup> Disc hemorrhage represents an important biomarker for disease progression in NTG,<sup>13</sup> but this is also true for OAG across the IOP spectrum (Fig. 10.11.1). The optic nerve head rim tissue can be focally eroded or exhibit diffuse thinning accompanied by extensive peripapillary atrophy, suggesting that distinct NTG endophenotypes do exist.<sup>11</sup> Determining whether macula or deep optic nerve head ocular coherence tomography will reveal distinct structural biomarkers associated with these NTG endophenotypes is currently a topic of active clinical research.

The visual field is more likely to show defects close to fixation, although this feature can be seen in glaucoma patients with IOP greater than 21 mm Hg.<sup>14</sup> Overall rates of visual field progression in untreated NTG vary considerably from –0.2 to greater than –2 dB per year on the Total Deviation plot.<sup>15</sup>

**Fig. 10.11.1** Optic disc of a patient who has normal-tension glaucoma. Note disc hemorrhage (H).

Over a period of 4–5 years, up to 50% of patients with untreated NTG show demonstrable progression.<sup>15</sup>

## DIAGNOSIS

Typically, patients are asymptomatic on presentation but will occasionally present with acute paracentral vision loss. It is critical to obtain past ocular, medical, and surgical histories (both ocular and nonocular) on all patients with new glaucoma. Past ocular history may reveal a history of uveitic glaucoma that could contribute to the appearance of a glaucomatous optic nerve at normal IOP. History of current and past medication use is also important, as pointed out in the differential diagnosis section below. For instance, a history of past steroid use may suggest prior steroid-induced glaucoma as a cause of apparent NTG. Vision and IOP are ophthalmic vital signs, and they are typically normal in NTG patients. There are no agreed-upon IOP criteria for NTG, although most recent publications require an IOP less than 22 mm Hg.

Confirmation of the diagnosis requires the following:

- Slit-lamp examination to rule out signs consistent with secondary glaucomas, such as prior pigment dispersion syndrome.<sup>16</sup>
- Gonioscopy to ensure the angle is not occludable.
- Fundus examination to detect signs of excavation of the cup and erosion of the neuroretinal rim while excluding signs of nonglaucomatous optic neuropathy, such as pallor out of portion to cupping<sup>17</sup> or chorioretinal lesions that either produce<sup>18,19</sup> or appear in a distribution that could mimic glaucomatous visual field defects.<sup>20</sup>
- Confirmation that the visual field defect conforms to the retinal nerve fiber layer territory.

Currently, ambulatory blood pressure measurements have no role in diagnosing NTG. Patients with pallor, cupping, or visual field defects respecting the vertical meridian should be considered for neuroimaging. In select instances, neuroimaging may also be indicated in younger patients or in those with a history of rapid visual field progression. Widespread use of neuroimaging to screen for intracranial pathology in patients with NTG should be discouraged. Occasionally, visual symptoms out of proportion to Snellen acuity (e.g., profound nyctalopia) or visual field loss not explained by the optic nerve head appearance may trigger a search for retinal disease, such as retinitis pigmentosa.<sup>21</sup>

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis of NTG is fairly extensive and summarized in [Box 10.11.1](#).

Many patients with NTG are discovered to have IOP greater than 21 mm Hg on more extensive IOP profiling. In another scenario, a patient with “progressive NTG” may have had a history of IOP greater than 21 mm Hg in the distant past, but often those records are unavailable. Careful history or examination in apparent NTG cases may reveal prior episodes of elevated IOP that likely produced glaucomatous optic neuropathy that is now nonprogressive.

“Myopic glaucoma” is emerging as a challenging condition that can be considered a form of open-angle glaucoma often associated with IOP less than 22 mm Hg. These patients can present in young adulthood,<sup>22</sup> and they have different IOP profiles versus NTG associated with focal disc notching.<sup>11</sup> The optic nerve can exhibit a variety of dysmorphic features, including peripapillary atrophy, tilt, and torsion.<sup>23</sup> Myopic glaucomatous optic neuropathy can be progressive and seems to be IOP sensitive.<sup>24</sup>

A variety of optic neuropathies can be misconstrued as NTG. Conversely, NTG can be incorrectly labeled as nonglaucomatous optic neuropathy. Dominant optic atrophy typically affects the maculopapillary bundle early on, producing temporal wedge cupping as opposed to vertical elongation of the cup.<sup>25</sup> NTG can be misconstrued as nonarteritic anterior ischemic optic neuropathy (AION) because of seemingly rapid onset altitudinal visual field loss, but a large cup volume and insidious progression can solidify a diagnosis of open-angle glaucoma at normal IOP. Conversely, arteritic AION commonly produces glaucoma-like cupping.<sup>26</sup> Superior segmental optic nerve hypoplasia (SSONH) typically is associated with a maternal history of type 1 diabetes mellitus and presents with stationary dense inferior visual field defects,<sup>27</sup> although coexistent SSONH and progressive NTG have been reported.<sup>28</sup> Documented recurrent intrathecal hypotension caused by malfunctioning ventriculo-extracranial shunts was associated with “NTG” (focal notching, disc hemorrhage, and superior paracentral scotoma were present) in a 27-year-old with a history of pinealoblastoma.<sup>29</sup> Last but not least, anterior visual pathway lesions can produce

### BOX 10.11.1 Differential Diagnosis of Normal-Tension Glaucoma

- High-tension glaucoma possibly misclassified as NTG:
  - More extensive intraocular pressure (IOP) profiling reveals elevated IOP greater than 21 mm Hg
  - Prior secondary glaucoma that has resolved like corticosteroid-induced or uveitic glaucoma
  - Prior high-tension glaucoma with progression despite IOP in the “normal range”
- Myopic optic nerve/retinal degeneration with varying degrees of optic nerve tilt and torsion
- Nonglaucomatous optic neuropathy:
  - Dominant optic atrophy
  - Prior nonarteritic or arteritic anterior ischemic optic neuropathy
  - Superior segmental optic nerve hypoplasia
  - Anterior visual pathway lesions
- Optic neuropathy related to documented low intracranial pressure
- Retinal based nerve fiber layer dropout:
  - Branch retinal artery occlusion
  - Toxoplasmosis
  - Cotton-wool spot
- Deep chorioretinal pathology mimicking nerve fiber pattern of visual field loss
  - Retinitis pigmentosa
  - Hydroxychloroquine toxicity
  - Cancer-associated retinopathy
- Drug-induced nerve fiber layer dropout
  - Methanol toxicity
  - Ethambutol toxicity
  - Vigabratin use
  - Others

cupping.<sup>30</sup> If these conditions are caught early, it can save lives and reverse visual field loss.

Retinal pathology, such as cotton-wool spots and toxoplasma lesions, has been reported to produce nerve fiber dropout. Because the retinal arterioles supply the superficial retina, a branch retinal artery occlusion can produce visual field loss mimicking glaucomatous defects.<sup>31</sup> Finally, deep chorioretinal pathology that produces photoreceptor dropout in a nerve fiber pattern can produce visual field loss that mimics glaucoma.

It is important to be cognizant of the wide range of agents that can produce toxic optic neuropathy when encountering a patient with cupping, pallor, and normal IOP.<sup>32</sup> Intentional or accidental methanol exposure produces profound visual loss related to an optic neuropathy characterized by acute disc swelling followed by cupping and atrophy.<sup>33</sup> An idiosyncratic response to the antituberculosis drug ethambutol can produce an optic neuropathy with propensity to involve the maculopapillary bundles.<sup>34</sup> Vigabratin is a gamma-aminobutyric acid (GABA) transaminase inhibitor used to treat epilepsy in children and adults that has direct retinal ganglion cell toxicity.<sup>35</sup> Interestingly, a genome-wide search revealed that aspects of the GABA metabolism pathway was associated with NTG.<sup>36</sup>

## SYSTEMIC ASSOCIATIONS

The stereotypical NTG patient is a thin woman with poorly perfused distal extremities and migraines, and this view is supported by clinic-based<sup>37,38</sup> and population-based studies,<sup>39,40</sup> although more research is needed to confirm these associations. Several studies indicate the presence of nail bed extravascular hemorrhages<sup>41,42</sup> and impaired flow-mediated vasodilation in NTG,<sup>43</sup> but these findings also apply to patients with open-angle glaucoma and IOP greater than 21 mm Hg. Impaired flow-mediated vasodilation is demonstrated by impaired brachial artery dilation in response to peripheral limb ischemia and is an indicator of poor communication between the vascular endothelium and the adjacent smooth muscle. A pharmacological interventional study highlighted this impaired communication—the brachial artery of patients with untreated NTG had impaired dilation in response to the universal vasodilator acetylcholine.<sup>44</sup> Overall, the lack of consensus on systemic disease or biomarkers for NTG should discourage nondirected workups to explain glaucomatous optic neuropathy occurring at normal IOP because these workups are typically negative and tend to waste resources.

## TREATMENT

The decision to treat NTG depends on the patient's age, disease severity at presentation, and level of IOP. It may be justified to observe an older patient with mild visual field loss and IOP in the low teens, especially because it is possible that the disease will progress slowly.<sup>15</sup> However, a young patient with significant visual loss involving fixation needs treatment, especially if the IOP is in the upper teens and/or there is a history of migraine as the latter was a risk factor for disease progression in the untreated arm of the Collaborative Normal Tension Glaucoma Treatment Study.<sup>14</sup>

### Lower Intraocular Pressure

There is no agreed-upon formula for setting target IOP goals in NTG. Randomized clinical evidence suggests that reduction of IOP by approximately 30% can slow disease progression in NTG.<sup>45,46</sup> The Low Pressure Glaucoma Treatment Study indicated that brimonidine was more effective than timolol in slowing disease progression in NTG,<sup>47</sup> suggesting that the former agent should be considered in the medical regimen, even though it is a drug with an unfavorable side-effect profile. The Early Manifest Glaucoma Treatment study indicated that laser trabeculoplasty plus topical beta-blocker did slow disease progression in the subset of patients with open-angle NTG.<sup>48</sup> Topical beta-blockers are not contraindicated in NTG, but they should be avoided at bedtime in all patients with glaucoma because they are ineffective when administered at this time. Adjustment of the target IOP should be guided by the degree of structural and functional progression and perhaps by the presence of disc hemorrhages, given that they are predictors of disease progression. Despite the expanded pharmacological regimen and repeatability of laser trabeculoplasty, trabeculectomy with mitomycin C is often needed because many patients with NTG progress despite IOP in the mid- to low teens. Cases series suggest that achievement of single-digit IOPs can slow disease progression in these cases.<sup>49,50</sup> There is little role for minimally invasive glaucoma surgery or glaucoma drainage devices to achieve these IOP levels.

Besides lowering of IOP, there is no proven nonophthalmic strategy to slow disease progression, and the existing data suggest that there is no proven strategy to halt disease progression entirely. Perhaps it is reasonable to suggest that systemic hypertension medicines be taken closer to dinner as opposed to bedtime, thus avoiding a nocturnal dip in blood pressure. It is unclear if lifestyle changes, such as altering sleep patterns, exercise, diet, or supplement use, will alter the natural history of NTG,

although there may be very good reason to adopt some of these behaviors. There is certainly a need to identify and validate new neuroprotection targets for NTG.

## COURSE AND OUTCOME

Predictors of disease progression include female gender, migraine, and disc hemorrhage.<sup>14</sup> Hospital-based data from Japan suggests that the 20-year rate of unilateral blindness from treated NTG was 10%, whereas the 20-year rate of bilateral blindness was only 1.4%.<sup>51</sup> Both patients and eye care providers should take some comfort in the latter statistic, but it should not serve to minimize the tremendous impact this disease has on vision and on activities of daily living.

# Angle-Closure Glaucoma

Dawn K.A. Lim, Victor T.C. Koh, Maria Cecilia D. Aquino, Paul T.K. Chew

10.12

**Definition:** A group of glaucomas characterized by elevated intraocular pressure as a result of mechanical obstruction of the trabecular meshwork by either apposition of the peripheral iris to the trabecular meshwork or by synechial angle closure.

## Key Features

- May be acute, subacute, or chronic.
- Acute angle closure may result in sudden pain, blurred vision, photophobia, colored halos around lights, ocular injection, headache, nausea, and vomiting.
- Subacute angle closure may be symptomatic with headaches, often mistaken for migraine, or may be asymptomatic.
- Chronic angle closure is generally asymptomatic.

## INTRODUCTION

Angle-closure glaucoma (ACG) was probably the first glaucoma to be recognized, when St. Yves, in 1722, described its symptoms, signs, and prognosis. It was not until 1923, however, when Raeder proposed that glaucoma be classified into two main types, one with a shallow anterior chamber and the other with a normal or deep chamber, that ACG was distinguished from open-angle glaucoma (OAG).

Population-based surveys of the prevalence of eye diseases in Europe<sup>1</sup> and the United States<sup>2-4</sup> suggest a much greater rate of OAG compared with ACG. Hence, little was published about the epidemiology of ACG, until recent epidemiological studies in Asia reported that Inuit,<sup>5,6</sup> Mongolians,<sup>7</sup> and Chinese<sup>8,9</sup> had significantly higher rates of ACG. It is now confirmed that not only is ACG more common than originally thought but that it is also associated with a much higher visual morbidity than OAG. ACG, if recognized and treated early, results in a good visual prognosis. Visual morbidity can be prevented if ACG is detected early; hence, early detection is key.

## EPIDEMIOLOGY AND PATHOGENESIS

### Prevalence

The prevalence of primary angle-closure glaucoma (PACG) in whites is reported to be 0.6% in Italy and 0.5% in Wales<sup>10</sup> in the 40+-year age group, and 0.1% in the 55+-year age group in Sweden.<sup>11</sup> The prevalence in Inuit is some 20–40 times higher.<sup>5,6,12,13</sup> The prevalence in East Asia and Southeast Asia has been reported to range from 1.4% to 4.3%, depending on the age group.<sup>7,9,14</sup>

Recent estimates based on various population-based studies of the prevalence of ACG suggest that in 2010, approximately 60.5 million people were affected by glaucoma (44.7 million with OAG and 15.7 million with ACG). This number is projected to increase to 79.6 million by 2020.<sup>15</sup> Of these, 26% will have ACG. The prevalence of ACG in 2010 among those 40 years and older was estimated to be 1.26% in China and 1.20% in Southeast Asia compared with 0.25% in Europe and 0.16% in Africa. Given the high prevalence of ACG in Asia,<sup>16,17</sup> Asians are predicted to represent 87% of those with ACG. Women will comprise 69.5% of cases of ACG because of the higher prevalence of the disease among women<sup>18</sup> and their greater longevity.

The World Health Organization currently ranks glaucoma as the second most common cause of blindness.<sup>19</sup> By 2010, bilateral blindness was estimated to be present in 3.9 million people with ACG. This is estimated to rise to 5.3 million people in 2020. The number of people blinded by ACG is nearly equal to the number blinded by OAG because of the higher morbidity of the former disease.

## Incidence

The incidence of acute PACG varies widely among different ethnic groups, from 4.7 (per 100 000 per year in the population 30 years and older) in Finland<sup>20</sup> to 11.4 in Japan,<sup>21</sup> and 12.2 in Singapore.<sup>18</sup>

## Risk Factors

1. Demographic factors:
  - a. Age (>60 years).
  - b. Female gender.
  - c. Chinese ethnic origin.<sup>22</sup>
  - d. Family history (especially first-degree relatives, because ocular anatomic features are inherited).
2. Anatomical factors<sup>23-27</sup>:
  - a. Shallow anterior chamber depth, especially peripherally.
  - b. Thick/anteriorly positioned/increased anterior curvature of lens.
  - c. Short axial length.
  - d. Small diameter/increased curvature of cornea.
  - e. Novel anterior-segment optical coherence tomography features.<sup>28-30</sup>
    - i. Anterior chamber angle characteristics:
      - Smaller trabecular-iris space area.
      - Smaller anterior chamber depth.
      - Increased lens vault.
    - ii. Iris characteristics:
      - Smaller curvature of the iris.
      - Increased iris thickness.
3. Precipitating factors:
  - a. Dim illumination (including extremes of temperature causing people to stay indoors).<sup>18,31-33</sup>
  - b. Drugs.
    - i. Anticholinergic agents (topical, e.g., atropine, cyclopentolate, and tropicamide; or systemic, e.g., antihistamine, antipsychotic [especially antidepressants], antiparkinsonian, atropine, and gastrointestinal spasmolytic drugs).
    - ii. Adrenergic agents (topical, e.g., epinephrine and phenylephrine; or systemic, e.g., vasoconstrictors, central nervous system stimulants, bronchodilators, appetite depressants, and hallucinogenic agents).
  - c. Emotional stress, excruciating pain (possibly due to mydriasis secondary to increased sympathetic tone).

ACG may be broadly subdivided into:

1. Primary ACG—no cause other than anatomical predisposition is identified.
2. Secondary ACG—angle closure is the result of a specific pathological condition that may arise in any part of the eye (e.g., neovascular glaucoma and anterior uveitis).

The traditional classification of ACG (Box 10.12.1) evolved from clinical observations and is based on symptoms that are subjective and may be highly variable. The lack of standardization and the frequent overlap in clinical presentation make it difficult for comparison in epidemiological studies. Furthermore, this form of classification does not offer any insight

### BOX 10.12.1 Traditional Classification of Angle-Closure Glaucoma (Based on Clinical Presentation and Symptomatology)

#### Acute

- Sudden onset of IOP elevation resulting from total angle closure, accompanied by symptoms of severe, usually unilateral, ocular pain, red eye, blurred vision, halos, headache (ipsilateral frontal), nausea, and vomiting

#### Subacute/Intermittent

- An episode of sudden IOP elevation that is spontaneously aborted so that symptoms are mild or even absent. Such subacute IOP elevations may be recurrent and therefore termed *intermittent angle closure*. Intermittent episodes can result in progressive PAS formation.

#### Chronic

- Chronic IOP elevation caused by the presence of PAS that permanently close the anterior chamber angle. Symptoms are usually absent. *Creeping angle closure* refers to chronic closure of angle where the root of the iris slowly creeps, or is pushed, into the depths of the narrow angle until it gradually smothers the outflow channels.<sup>23</sup>

#### Latent

- Evidence that an open but narrow angle can and does close under certain circumstances. Asymptomatic, but PAS is often found on gonioscopy.

IOP, intraocular pressure; PAS, peripheral anterior synechiae.

### BOX 10.12.2 Classification Based on Natural History

#### Primary Angle Closure Suspect (PACS)

- An eye in which appositional contact between the peripheral iris and posterior trabecular meshwork is present or considered possible, in the absence of elevated IOP, PAS, disc, or VF changes. Epidemiologically, this has been defined as an angle in which 180–270° of the posterior trabecular meshwork cannot be seen gonioscopically.

#### Primary Angle Closure (PAC)

- PACS with statistically raised IOP and/or primary PAS, without disc or VF changes.

#### Primary Angle-Closure Glaucoma (PACG)

- PAC with glaucomatous optic neuropathy and corresponding VF loss.

IOP, intraocular pressure; PAS, peripheral anterior synechiae; VF, visual field. Adapted from Foster PJ, Buhrmann RR, Quigley HA, et al. The definition and classification of glaucoma in prevalence surveys. *Br J Ophthalmol* 2002;86:238–42.

as to the natural history of the disease or the presence or absence of glaucomatous optic neuropathy and is therefore not useful for visual prognostication. Hence, the International Society of Ophthalmic Epidemiology developed a classification that is based on the natural history of the disease (Box 10.12.2).<sup>34</sup>

This classification is evidence based and is therefore more objective. These definitions have been widely used in the classification of subjects in research and have been adopted in the Asia Pacific Glaucoma Guidelines. However, it does not identify the pathophysiological mechanism that is responsible for angle closure and hence does not facilitate the clinician in choosing an appropriate treatment. A classification devised by Ritch and colleagues<sup>35</sup> is useful for this purpose and should be used in parallel (Box 10.12.3; Figs. 10.12.1 to 10.12.7).

## Pupillary Block

Pupillary block represents the most common mechanism underlying angle closure. In pupillary block, iridolenticular contact at the pupil limits the flow of aqueous from its site of production at the nonpigmented ciliary epithelium to the anterior chamber, resulting in a pressure gradient between the posterior and anterior chambers that further pushes the iris anteriorly. Anterior bowing of the peripheral iris narrows the angle and may then cause iridotrabecular apposition and angle closure. Laser iridectomy re-establishes aqueous flow from the posterior to the anterior chamber and

### BOX 10.12.3 Classification Based on Anatomic Levels of Obstruction to Aqueous Flow (Pathophysiology of Angle-Closure Glaucoma)

Apposition of the iris to the trabecular meshwork in angle-closure glaucoma may be caused by forces acting at four anatomical levels:

#### Iris

- Pupillary block (see Fig. 10.12.1)
- <sup>a</sup>Nonpupillary block/angle crowding mechanisms—e.g., thick peripheral iris roll (see Fig. 10.12.2)
- Contraction of fibrovascular membrane in neovascular glaucoma
- Contraction of fibrin in angle secondary to anterior uveitis or hyphema
- Endothelial proliferation (iridocorneoendothelial syndromes)
- Epithelial downgrowth

#### Ciliary Body

- Plateau iris configuration (forward rotation of the ciliary body or anterior position of ciliary processes) (see Fig. 10.12.3)
- Iridociliary cysts (pseudo-plateau iris) (see Fig. 10.12.4)

#### Lens

- Phacomorphic glaucoma (thick lens) (see Fig. 10.12.5)
- Phakotopic glaucoma (anteriorly positioned lens)
- Subluxed lens (e.g., pseudo-exfoliation syndrome, traumatic) (see Fig. 10.12.6)

#### Vectors Posterior to Lens

- Aqueous misdirection (malignant glaucoma) (see Fig. 10.12.7)
- *Serous or hemorrhagic choroidal detachment or effusion*
- *Space-occupying lesion (gas bubble, vitreous substitutes, tumor)*
- *Retrolenticular tissue contracture (retinopathy of prematurity, persistent hyperplastic primary vitreous)*

<sup>a</sup>Nonpupillary block/angle crowding mechanisms have been included here as an addition to Ritch's classification.

Secondary causes of angle closure are shown in italics.

relieves the pressure gradient, thereby allowing the iris to flatten and the angle to widen.

## Nonpupillary Block Mechanisms

The variable efficacy of laser iridectomy in many cases of angle closure as well as ultrasound biomicroscopy imaging suggests that pupillary block may not be the only mechanism responsible. The role of angle crowding, for example, that caused by a thick peripheral iris roll, has been increasingly recognized in many cases of angle closure. This has been added to Ritch's classification, for the sake of completeness. In many such cases, the peripheral iris stroma is thick. Upon pupil dilatation, the peripheral iris bunches up. If the angle is already narrow, this thick peripheral iris roll may become apposed to the trabecular meshwork and result in angle closure.

## Plateau Iris Configuration

On gonioscopy, the iris assumes a steep approach at its insertion before flattening centrally. The peripheral iris is forced into the angle by anterior rotation of the ciliary body or anteriorly positioned ciliary processes. The development of angle closure either spontaneously or after pupil dilatation in an eye with plateau iris configuration, in the presence of a patent laser iridectomy, is termed *plateau iris syndrome*. Disorders of the ciliary body, such as iridociliary cysts or tumors, may result in a similar plateau iris configuration. This is termed *pseudo-plateau iris*.

## Aqueous Misdirection

This condition, also called *malignant glaucoma* or *ciliary block glaucoma*, is characterized by shallowing or flattening of the anterior chamber, accompanied by a rise in intraocular pressure (IOP). It is typically seen in the post-operative period but can arise spontaneously. It is believed that aqueous passes posteriorly to the posterior segment instead of anteriorly to the posterior chamber because of obstruction to flow caused by the anterior rotation of ciliary processes resulting in their apposition to the lens equator in the phakic eye, or against the anterior hyaloid in the aphakic eye. The

**Fig. 10.12.1 Pupillary Block.** (A) Photograph of eye with pupillary block. (B) Anterior segment optical coherence tomography image. (C) Ultrasound biomicroscopy image.

accumulation of aqueous in the posterior segment causes an anterior displacement of the lens–iris diaphragm. Laxity of the lens zonules allowing this forward movement has also been suggested to play a role in the development of this condition.

The term “malignant” was used originally to describe its poor response to conventional miotic treatment. Early recognition of aqueous misdirection is important in reducing its morbidity. Management involves prompt medical treatment with topical cycloplegic agents, such as atropine, which increases zonular tension and pulls the lens posteriorly. Atropine 1% may be given 2–4 times a day for weeks to months or even years. Topical beta-blockers, alpha-2-agonists, and carbonic anhydrase inhibitors may be used to decrease aqueous production and lower the IOP. Hyperosmotic agents may also be used to decrease the vitreous volume. If the condition persists beyond 5 days despite adequate medical therapy, laser or surgical intervention must be considered. Neodymium:yttrium–aluminum–garnet (Nd:YAG) laser has been demonstrated to be effective in the pseudo-phakic and aphakic eye by disrupting the anterior hyaloid face, especially peripherally. Aspiration of the anterior vitreous, anterior pars plana vitrectomy, or

**Fig. 10.12.2 Peripheral Iris Roll.** Anterior segment optical coherence tomography images of the same eye taken in (A) light and (B) dark conditions.

**Fig. 10.12.3 Plateau Iris Configuration.** Ultrasound biomicroscopy image.

lens extraction with a posterior capsulotomy may be performed; however, disruption of the hyaloid face is key to the success of this procedure. A prophylactic laser iridectomy should also be considered for the fellow eye, as there is a significant risk that aqueous misdirection may occur following intraocular surgery in that eye.

## DIAGNOSIS

### External Examination

The majority of people with PACG do not experience any symptoms.<sup>3,7</sup> Characteristic findings in a patient presenting during an acute angle-closure attack include conjunctival hyperemia, a hazy cornea with corresponding decreased visual acuity (Fig. 10.12.8), and a mid-dilated nonreactive or sluggish pupil. The pupil is mid-dilated because of ischemic paralysis of the iris sphincter muscles occurring as a result of the greatly elevated IOP. With infarction of these muscles, the pupil does not return to its normal appearance, even when the IOP has been lowered, and iris whorling may become evident. Digital palpation of the eye through a closed eyelid reveals a firm (often rock-hard) eye. The patient may also experience bradycardia or arrhythmia.

**Fig. 10.12.5 Phacomorphic glaucoma.**

**Fig. 10.12.8 Acute angle-closure glaucoma.**

**Fig. 10.12.6 Anteriorly subluxed lens.**

## Penlight Examination

When a slit lamp or gonioscope is unavailable, a penlight may be used to estimate the anterior chamber depth. This test is performed by shining the penlight from the temporal side of the eye. A flat iris with a deep anterior chamber would allow the nasal iris to be illuminated, whereas an iris that is convex with a correspondingly shallow anterior chamber would block the illumination, causing the nasal iris to be in shadow.

## Slit-Lamp Examination

In acute angle closure, the cornea usually appears hazy because of epithelial and stromal edema secondary to the acute rise in IOP with mid-dilated pupil and peripherally shallow anterior chamber. Iris bombé is usually present as a result of pupillary block. Iris whorling (sectoral infarction of the iris sphincter leading to torsion of the iris), patchy iris stromal atrophy (Fig. 10.12.9), and lens glaucomflecken (Fig. 10.12.10) (small gray-white anterior subcapsular or capsular opacities in the pupillary zone resulting from infarction of lens fibers) may also be evident if the patient has had an acute rise in IOP previously.

Both central and peripheral anterior chamber depth (ACD) may be assessed at the slit lamp. Although the central ACD only weakly correlates with the angle width,<sup>36</sup> peripheral ACD estimation appears to perform well

**Fig. 10.12.9** Iris whorling and atrophy.

**Fig. 10.12.10** Glaucomflecken.

in the detection of occludable angles.<sup>37</sup> The van Herick technique<sup>38</sup> (Fig. 10.12.11) is useful for estimating the peripheral ACD. In this technique, the illumination column is offset from the axis of the microscope by 60°. The brightest, narrowest possible vertical beam of light is directed at the temporal limbus, perpendicular to the ocular surface. Viewed from the nasal aspect, the peripheral ACD is compared with the adjacent corneal thickness that is illuminated by the light beam. The angle may be occludable if the peripheral ACD is less than one fourth of the corneal thickness. The limbal chamber depth method of grading the peripheral anterior chamber is a recent modification of the van Herick test.<sup>39</sup> Instead of the four grades used in the van Herick method, it has seven grades that are expressed as a percentage fraction of the thickness of the adjacent cornea: 0%, 5%, 15%, 25%, 40%, 75%, and 100%. The limbal chamber depth method has been demonstrated to perform better in the detection of established PACG and is now widely used in epidemiological research.

Slit-lamp examination should also include a thorough check for the presence of any inflammation, hyphema, and cataract or subluxed lens. IOP is often severely elevated (often >40 mm Hg). Careful examination of the optic disc should also be performed to detect any evidence of glaucomatous optic neuropathy.

## Gonioscopy

Careful gonioscopic examination of the angle is vital to make the diagnosis of angle closure. This is best performed using first a two-mirror goniolens

**Fig. 10.12.11** Van Herick technique.

(e.g., Goldmann) to avoid artifactual distortion of the angle caused by inadvertent pressure on the cornea, followed by a four-mirror goniolens (e.g., Sussman, Zeiss) that allows indentation gonioscopy to reveal whether any closure is caused by peripheral anterior synechiae (PAS) or is merely appositional. Gonioscopy should be performed in a dark room using a 1-mm light beam reduced to a very narrow slit, and care should be taken to avoid any light falling on the pupil, which might otherwise cause pupil constriction and angle widening. The vertical light beam should be offset horizontally for the assessment of the superior and inferior angles, and the horizontal beam should be offset vertically for the nasal and temporal angles. Assessment of the angles should be carried out at  $\times 25$  magnification. Although currently the reference standard for angle assessment, gonioscopy remains a subjective technique that depends on the experience of the clinician as well as conditions of illumination.

Various grading systems, including Scheie, Shaffer, and Spaeth, have been proposed for the recording of gonioscopic findings. These gonioscopic grades provide an index of the likelihood of angle closure.<sup>40</sup> With the Scheie grading system, there is a high risk of angle closure in eyes that are graded III (only anterior TM and Schwalbe's line visible) or IV (only Schwalbe's line visible). Shaffer grades I (angle width 0–10°) and II (10–20°) are associated with risk of angle closure, while an angle with a Spaeth grade of B20s (iris insertion behind Schwalbe's line, angle width 20°, steep peripheral iris contour) may be potentially occludable. “Biometry gonioscopy,” where a reticule in the eyepiece of the slit lamp is used to measure the distance from the iris insertion to Schwalbe's line, has also been suggested as a more reproducible and objective method of gonioscopy.

## Other Imaging Techniques

### Ultrasound Biomicroscopy

Ultrasound biomicroscopy (UBM) (Fig. 10.12.12) allows dynamic high-resolution imaging of the anterior segment structures, including the anterior chamber angle, the iris, iris–lens interaction, and ciliary body. Thus it can help elucidate the underlying mechanism of angle closure in most cases, including plateau iris syndrome and iridociliary cysts, thereby allowing the appropriate treatment to be given. It is also useful in demonstrating angle occludability when performed in a dark room. The major disadvantages of UBM are that it is a time-consuming procedure, and it requires a skilled operator and contact with the patient's eye. Its high cost also limits its availability.

### Anterior-Segment Optical Coherence Tomography

Time-domain anterior segment optical coherence tomography (AS-OCT) (Fig. 10.12.13) using light of wavelength 1310 nm has enabled high-speed imaging of the anterior segment structures. It is an easy technique to master and does not require contact with the patient's eye. A comparison with gonioscopy has found that it may be superior in its ability to detect angle occludability.<sup>41</sup> It suggests that gonioscopy (which uses visible light) may be underestimating angle occludability, even when performed in ideal darkroom conditions. AS-OCT has also been reported to be similar to UBM in quantitative anterior chamber angle measurement and detection of narrow angles.<sup>42</sup> More recently, the use of swept-source AS-OCT has the

**Fig. 10.12.12 Ultrasound Biomicroscopy.** (A) Ultrasound biomicroscopy (UBM) device. (B) UBM image of the anterior chamber angle.

added advantage of higher resolution, faster scanning speed, 360° imaging of the anterior chamber angles (Fig. 10.12.14A–B).<sup>43</sup>

### Provocative Tests

Historically, provocative tests were used to attempt to trigger angle closure in primary angle-closure suspects (PACS) to identify patients for whom treatment is then recommended. These included the darkroom prone test and pharmacological pupil dilatation. However, these tests may not be easily reversible and are associated with high false-positive and false-negative rates. They are therefore seldom practiced now.

## DIFFERENTIAL DIAGNOSIS

Differential diagnosis includes the following:

- Secondary ACG (shown in *italics* in Box 10.12.3).
- Other causes of headache (e.g., migraine or cluster headache).

## MANAGEMENT OF ACUTE ANGLE CLOSURE

Acute angle closure is an ophthalmological emergency. Measures should be taken within minutes to hours to lower the IOP and break the attack, followed by identification of the mechanism of angle closure and appropriate treatment to widen the angle.

Corneal indentation with a four-mirror gonioscope or cotton-tipped applicator may be attempted at 30-second intervals to force open an area of appositionally closed trabecular meshwork that will allow some aqueous

**Fig. 10.12.13 Anterior-segment optical coherence tomography (AS-OCT).** (A) AS-OCT device (Carl Zeiss Meditec). (B) AS-OCT image of anterior chamber.

to exit the eye.<sup>44</sup> However, this technique may cause pain and momentary further increases in IOP. Hence, it may not be suitable in all cases.

Recent studies suggest that laser iridoplasty may be a useful alternative to conventional systemic medication as a first-line treatment in the management of acute angle closure, especially when certain medications are contraindicated, for example, in patients with pre-existing asthma, or cardiac or renal disease.<sup>45,46</sup>

### After 1 to 2 Hours

- If the attack is broken and corneal edema resolves, perform laser iridectomy. Laser iridoplasty should be performed in addition in cases of plateau iris syndrome, and can also be considered where the angle remains narrow despite a patent laser iridectomy.
- If the attack is not broken but the cornea is clear, laser iridectomy should be performed.
- If the attack is not broken and the cornea is still hazy, laser iridoplasty is performed first, followed by laser iridectomy later when corneal edema resolves.<sup>47–49</sup>

Laser iridectomy is the definitive treatment in ACG and results in significant angle opening in the majority of cases.<sup>50</sup>

Anterior chamber paracentesis has also been suggested as an alternative to break the attack if all else fails, especially if laser is unavailable.<sup>51</sup>

### Later

If the attack is still not broken, consider surgery (lens extraction if the lens is the causative factor, or surgical peripheral iridectomy). The fellow eye should be evaluated by gonioscopy for risk of angle occludability and treated with prophylactic laser iridectomy (Box 10.12.4)<sup>52,53</sup>, if necessary. Topical corticosteroids should be continued four times a day for about 5–7

**Fig. 10.12.14** Swept-source anterior-segment optical coherence tomography (AS-OCT). (A) Cross-sectional AS-OCT image (CASIA SS-1000, Tomey, Japan). (B) Swept source 3D AS-OCT image.

days after laser iridectomy, and antiglaucoma medications discontinued when IOP returns to normal.

## Even Later

A repeat gonioscopic examination should be carried out after laser iridectomy has been successfully performed to assess if the eye is still at risk of angle closure as well as to document the presence and extent of PAS. Once it is deemed safe to dilate the pupil, a dilated ocular examination should also be performed to assess the optic nerve status and to exclude any secondary causes of angle closure that may need further treatment.

The IOP should be monitored closely in the first 12 months after the attack to detect any asymptomatic rise in IOP early.

## MANAGEMENT OF CHRONIC ANGLE-CLOSURE GLAUCOMA

In the case of a patient presenting with elevated IOP, in the presence of partially or totally occluded angles with PAS and glaucomatous optic neuropathy, medical treatment (see below) to lower IOP should be commenced. Laser iridectomy and laser iridoplasty may be considered, although the effects of laser iridoplasty in the presence of extensive synechial closure may be questionable. Gonioscopy should be repeated to assess angle width and the extent of PAS. If IOP continues to be inadequately controlled or if there is any evidence of progression in optic nerve or visual field damage, then the decision to go on to surgical treatment (see below) should be taken.

## MANAGEMENT OF ANGLE-CLOSURE GLAUCOMA

### Medical Treatment

In acute angle closure, topical beta-blockers, alpha-2-agonists, and carbonic anhydrase inhibitors may be used to lower the IOP to a level where corneal edema resolves, allowing laser iridectomy to be performed. Topical pilocarpine (2% or 4%) can also be used in the acute setting to constrict

## BOX 10.12.4 Laser Iridectomy

### Indications

- AC
- ACG
- ACS, especially if:
  - AC in fellow eye
  - Family history of ACG
  - Need for repeated dilated examinations
  - Poor access to regular ophthalmic care

### Procedure

1. Before laser:
  - Instill topical 2% or 4% pilocarpine and alpha-2-agonist and/or oral acetazolamide 30–60 minutes prior to the procedure. This helps to reduce the occurrence of postlaser IOP spike
  - Topical anesthesia
2. Laser:
  - Abraham/Wise iridectomy lens with coupling fluid
  - Choose iris crypt or an area of thin iris. Avoid level of tear meniscus formed by lid and globe. Aim at peripheral iris, avoiding cornea arcus.
  - Nd:YAG 2–5 mJ (use minimum energy), 1–3 pulses/burst
  - Argon laser 700–1100 mW, 50  $\mu$ m spot size, 100 ms, 10–20 burns can be used prior to Nd:YAG laser in a thick iris to photocoagulate and thin the iris stroma, thereby also reducing the risk of iris bleeding<sup>58</sup>
  - Endpoint—iris pigment plume, lens visible through iridectomy, LI size of about 150–200  $\mu$ m.<sup>59</sup> Brown Asian irides are thicker than blue ones and probably require a larger iridectomy
3. After laser:
  - Check IOP 1 hour after laser to exclude any IOP spike

### Complications

- Corneal endothelial burns (with argon)
- Iris hemorrhage from site of LI (with Nd:YAG)—applying pressure on the globe with the laser lens is usually sufficient to stop the hemorrhage
- IOP spike
- AC inflammation with closure of iridectomy, formation of posterior synechiae, or raised IOP
- Cataract formation
- Corneal endothelial decompensation, malignant glaucoma, retinal damage, cystoid macular edema (all rare)

AC, Angle closure; ACG, angle-closure glaucoma; ACS, angle-closure suspect; IOP, intraocular pressure; LI, laser iridectomy.

the pupil in an attempt to pull the peripheral iris away from the trabecular meshwork to re-establish aqueous outflow. Pupil constriction also helps to stretch the iris so that laser iridectomy may be performed more easily through a thinner iris. Pilocarpine is effective in inducing miosis only when iris ischemia is relieved (i.e., when IOP falls to <50 mm Hg). Pilocarpine should, however, be avoided in cases where it may exacerbate pupillary block, such as in pseudo-exfoliation, phacomorphic glaucoma, and aqueous misdirection, that is, where angle closure is secondary to lens-induced or retrolenticular mechanisms. Intravenous/oral acetazolamide 5–10 mg/kg (alternatives: hyperosmotic agents, e.g., intravenous 20% mannitol 1–2 g/kg, oral 50% glycerol 1–1.5 g/kg [contraindicated in diabetics], oral isosorbide 1.5–2.0 g/kg) may also be given to lower IOP for as long as not medically contraindicated. Topical corticosteroids are added to relieve ocular congestion and inflammation.

Once the patient has been treated with laser iridectomy (and laser iridoplasty, where indicated), long-term medical treatment can be used if IOP control remains suboptimal. Recent studies have demonstrated that prostaglandins, such as latanoprost, bimatoprost, and travoprost, are also effective in lowering IOP in chronic PACG, even in the presence of 360° of PAS.<sup>45,53–59</sup> Their delayed onset of action, however, precludes their use in the acute setting.

## Laser Treatment

A summary of the indications, procedure, and complications of laser iridectomy is given in Box 10.12.4 (Fig. 10.12.15) and of laser iridoplasty in Box 10.12.5 (Fig. 10.12.16).

Fig. 10.12.15 Laser iridectomy.

The long-term efficacy of laser iridoplasty has not been well established.

## Surgical Treatment

The main aims and indications for surgical treatment for angle closure are given in Box 10.12.6.

### Surgical Iridectomy

Since the advent of laser iridectomy, surgical peripheral iridectomy is now seldom performed. However, it may still be useful occasionally where the cornea fails to clear sufficiently for laser iridectomy to be performed, or in the case of a patient who is unable to cooperate with the laser procedure.

Fig. 10.12.16 Laser iridoplasty (performed in addition to laser iridectomy).

### BOX 10.12.5 Laser Iridoplasty

#### Indications

- Angle still occludable after laser iridectomy (e.g., plateau iris)
- In acute angle closure, to help break the attack where medical therapy has failed or is contraindicated
- To facilitate access to trabecular meshwork for laser trabeculoplasty

#### Procedure

1. Before laser:
  - As for laser iridectomy
2. Laser:
  - Abraham/Wise/Goldmann three-mirror lens
  - Aim at iris as peripheral as possible, outside of any cornea arcus
  - Argon green or blue-green, or diode 200–500 mW, 100–500  $\mu$ m spot size, 0.2–0.5 seconds, single row of 6–10 burns per quadrant over 180–360°
  - Endpoint—iris stromal contraction accompanied by progressive peripheral anterior chamber deepening with increasing number of burns
3. After laser:
  - As for laser iridectomy. Topical corticosteroids four times/day for 7 days.

#### Complications

- Corneal endothelial burns
- Iritis
- Intraocular pressure spike
- Peripheral anterior and/or posterior synechiae

A 2–3 mm partial-thickness incision (to about two thirds of the corneal thickness) is made, usually in the superotemporal peripheral cornea or at the limbus after a limited conjunctival peritomy. The anterior chamber is then entered with the blade held vertically. A toothed forceps is used to hold the prolapsed iris, and Vannas scissors are used to excise it. Neither

**Fig. 10.12.17** Pre-phacoemulsification (A) versus postphacoemulsification (B) with intraocular lens implant. Anterior-segment optical coherence tomography images.

### BOX 10.12.6 The Main Aims and Indications for Surgical Treatment in Angle Closure

#### Main Aims

- To decrease IOP and reduce risk of optic nerve damage
- To prevent progressive angle closure
- To reduce risk of acute angle closure

#### Indications

- Inadequate control of IOP, with progression of optic nerve or visual field damage, despite medical and laser treatment
- Poor compliance or intolerance to medical treatment
- Inability to cooperate with laser treatment
- Worsening angle closure and/or PAS
- Presence of significant cataract impairing vision

IOP, Intraocular pressure; PAS, peripheral anterior synechiae.

forceps nor scissors enter the anterior chamber, thus avoiding any risk of damage to the lens or other structures. The edges of the incision are then stroked to encourage the iris to retract into the anterior chamber, and the corneal incision is closed with one or two 10-0 nylon sutures.

### Lens Extraction

Removal of the lens, especially if there is any evidence of cataract, may be helpful in cases where either the lens thickness or anterior position is thought to be the main mechanism underlying the acute episode of angle closure (Fig. 10.12.17). However, care must be taken during surgery because these eyes are usually associated with high IOP, shallow anterior chambers, cloudy cornea, decreased corneal endothelial cell counts, floppy iris resulting from previous ischemia, posterior synechiae, bulky lens, lax lens zonules, and a high risk of malignant glaucoma. Reports of phacoemulsification combined with goniosynechialysis, in the presence of peripheral anterior synechial closure, have been encouraging.<sup>60,61</sup> A recent randomized controlled trial demonstrated that there could be a role for early lens extraction in eyes where the lens is a significant component of angle closure.<sup>62</sup>

### Goniosynechialysis

This is usually performed in combination with lens extraction, and involves mechanical stripping of PAS away from the trabecular meshwork using viscoelastics or an irrigation cyclodialysis spatula.<sup>60,61</sup>

### Trabeculectomy

Trabeculectomy is performed similarly as for OAG, with the exception that a surgical peripheral iridectomy should always be performed at the time of trabeculectomy. In addition, the use of antimetabolites should be considered. Trabeculectomy, alone or in combination with lens extraction, should be considered after the acute attack of angle closure, if the IOP control remains suboptimal despite medical and laser treatment, especially in more advanced cases of ACG that are associated with PAS, optic nerve, or visual field damage. In acutely inflamed eyes, trabeculectomy has been reported to have low success rates.<sup>63</sup>

### Glaucoma Drainage Implant

This may be considered in chronic ACG where trabeculectomy has failed to control the IOP or in eyes that are deemed to be at high risk of failure with trabeculectomy.

### Cyclodestructive Procedures

Cyclodestructive procedures, such as transscleral cyclophotocoagulation, are used for ACG eyes with end-stage disease that have poor visual potential, especially if they are symptomatic because of high IOP.

### Micropulse Laser

A recent advancement, in the form of micropulse laser treatment to the eye via trans-pars plana treatment with a modified contact probe is currently available for use. Compared with conventional cyclodestructive procedures, this new form of micropulse laser therapy has been reported to be better tolerated because there are no severe complications, such as hypotony, loss of vision, and phthisis bulbi.<sup>64</sup>

Caution must be exercised when performing surgery in eyes with ACG because of the increased risk of malignant glaucoma.<sup>65</sup> In addition, the use of topical corticosteroids after laser treatment or surgery in these patients may be associated with corticosteroid-induced IOP elevation following an attack of ACG.<sup>66</sup>

## PROGNOSIS

Angle closure is associated with good visual prognosis, provided it is detected early and the appropriate treatment given. Of the cases presenting with acute primary angle closure (PAC), 42%–72% can be satisfactorily treated with laser iridectomy alone,<sup>67,68</sup> and 60%–75% of such patients recover without optic disc or visual field damage, if the IOP is promptly and adequately controlled.<sup>69</sup> However, a longer duration of the angle-closure attack or a history of intermittent angle-closure episodes is often associated with the need for additional medical or even surgical therapy.<sup>70–72</sup> The presence of a significant amount of PAS, a higher presenting IOP, and a larger cup-to-disc ratio on presentation are other predictors of inadequate IOP control despite a patent laser iridectomy.<sup>73–75</sup> Most patients who develop a rise in IOP after laser iridectomy do so within the first 6 months.<sup>72</sup> Once glaucomatous optic neuropathy and visual field damage have developed, 94%–100% may require further surgical treatment to control IOP.<sup>76</sup>

In patients presenting with unilateral acute PAC, prophylactic laser iridectomy in the fellow eye also appears to be safe and effective in preventing acute PAC in 100% and in preventing long-term rise in IOP in 89%.<sup>77</sup> However, the fact that a small proportion of fellow eyes did develop a pressure rise despite the presence of a patent laser iridectomy emphasizes the importance of long-term monitoring.

There has been a paucity of longitudinal studies looking at the rate of progression from PACS to PAC and PACG. One population-based study in Greenland<sup>78</sup> reported an incidence of PAC (in subjects who progressed from PACS) of 16% over 10 years, and Thomas et al.<sup>79</sup> reported that 22% of PACS developed PAC after 5 years, and 28% of PAC subjects went on to develop PACG<sup>80</sup> over a similar period. However, more research needs to be done to understand the natural history of this disease better.

## ACKNOWLEDGMENTS

The team would like to thank Dr. Jovina L.S. See for her contributions to the earlier edition of this chapter.

# Glaucoma Associated With (Pseudo)-Exfoliation Syndrome

10.13

Robert Ritch, Bryan S. Lee, Thomas W. Samuelson

**Definition:** Exfoliation syndrome (also referred to as *pseudo-exfoliation syndrome*) is a systemic disorder with multiple ocular associations, the most important of which is glaucoma secondary to the deposition of whitish, fibrillar material on and within the structures of the anterior segment.

## Key Features

- Exfoliation material is most often seen on the anterior lens capsule and pupillary border of the iris. It can be seen in the angle and on the cornea.
- Most commonly associated with open-angle configuration and increased angle pigmentation, but also a common cause of narrow and closed angles.
- Intraocular pressure can be normal to markedly elevated.

## Associated Features

- Increased irregular angle pigmentation, pigment on Schwalbe's line, and Sampaolesi's line (strongly indicates diagnosis) on peripheral corneal shelf.
- Pigment dispersion in anterior chamber after pupillary dilation, often with an associated rise in IOP.
- Zonular laxity and fragmentation predisposing to both lens and in-the-bag IOL subluxation, surgical complications, and anterior chamber shallowing.
- Iris sphincter region transillumination defects, relative pupillary miosis, and often poor dilation, especially during phacoemulsification.
- Defective blood–aqueous barrier.

## INTRODUCTION

Exfoliation (or pseudo-exfoliation) syndrome (referred to herein as *exfoliation syndrome* [XFS]), is an ocular manifestation of an age-related systemic disorder of the extracellular matrix characterized by the production and progressive accumulation of a fibrillar extracellular material in many ocular and systemic tissues. XFS appears to be a disease of elastic tissue microfibrils. It is the most identifiable cause of secondary open-angle glaucoma worldwide, comprising the majority of cases in some countries.<sup>1</sup>

First described in 1917 by Lindberg in Finland, the importance of XFS and the differences from primary open-angle glaucoma (POAG) were largely overlooked until the twenty-first century. The diagnosis was largely missed because of failure to examine the lens after pupillary dilation and because of failure to recognize its importance. It is a disease with specific genetic, cell biological, and pathophysiological mechanisms and is related to other glaucomas only in the sense that it causes high-tension glaucoma as a result of blockage and dysfunction of the trabecular meshwork. Rapidly increasing research has revealed new findings in genetics, biochemistry, and cellular pathophysiology, opening the door to the development of new approaches to treatment. XFS is now regarded as potentially preventable and eventually reversible or even curable.<sup>2,3</sup>

The incidence of XFS increases steadily with age in all populations. It presents unilaterally in about two thirds of cases, and 50% of uninvolved fellow eyes will develop it in 15 years. Exfoliation material is found in the conjunctiva and iris in the uninvolved eye, but why it does not develop

clinically bilaterally is a question of renewed importance. Its prognosis has been described as worse than that of POAG, with greater intraocular pressure (IOP) and visual field loss at the time of presentation, poorer response to therapy, greater need for surgery, and greater progression to blindness. About one third of patients with XFS will develop secondary glaucoma.<sup>4,5</sup>

## EPIDEMIOLOGY AND GENETICS

Formerly thought to be primarily a disease found in Scandinavian countries, XFS exists worldwide, with widely varying prevalence rates. It is common in Scandinavia, Celtic populations, across the Mediterranean, and in the Middle East and South Asia, but its prevalence tapers off and is uncommon in China. It has been described as being common among South African Bantu, Ethiopians, Navahos, and other groups.

The prevalence of XFS in patients with glaucoma is significantly higher than in age-matched nonglaucomatous populations. Approximately 25%–50% of patients with XFS have or will develop elevated IOP, and one third of these will develop glaucoma. There is approximately six times the odds of finding elevated IOP in eyes without XFS. It has been estimated (Lindberg Society) that clinically detectable XFS affects approximately 60–80 million people, or nearly 20% of the world's population with open-angle glaucoma.<sup>1,5-10</sup>

In 2007, Thorleifsson et al. reported that single nucleotide polymorphisms (SNPs) in the lysyl oxidase-like protein 1 (LOXL1) gene conferred a risk for exfoliation glaucoma (XFG) but not POAG in patients from Iceland and Sweden.<sup>11</sup> A single nucleotide polymorphism (SNP) in the first intron tagged susceptibility to XFG and was equally present in XFS. Actual XFG was associated with haplotypes formed by two nonsynonymous SNPs in the first exon of LOXL1. Association studies of these two SNPs showed that the highest risk haplotype conferred a 700-fold greater risk of XFS than the lowest risk haplotype. The two higher-risk haplotypes explained over 99% of XFG in Caucasians. However, the normal population without XFS also has a high prevalence of these haplotypes, including populations in which XFS is rare. The SNPs are associated, but not causative. The LOXL1 protein is involved in cross-linking of elastin fibers in the extracellular matrix.<sup>12</sup> In 2015, a significant association between *CACNA1A*, a gene involved in calcium transport, and XFS was reported.<sup>13</sup> Calcium is necessary for LOXL1 binding to the extracellular matrix. In 2017, five new susceptibility genes and a protective locus were reported.<sup>14,15</sup> It remains to be discovered how these are related, but further work may provide ways to genetically regulate LOXL1 production. Gene–environment interactions, including caffeine intake, ultraviolet radiation, and latitude of birth, and early life also appear to influence the manifestation of XFS in addition to racial and ethnic variations.<sup>7,16</sup>

## CLINICAL PRESENTATION AND OCULAR MANIFESTATIONS

XFS is diagnosed by the presence of typical whitish, fibrillogranular exfoliation material (XFM) on the anterior lens surface or pupillary border (Fig. 10.13.1). This consists of three zones: a central disc, an intermediate clear zone, and a peripheral granular zone. The XFM is produced primarily by the iris pigment epithelium, ciliary pigment epithelium, and anterior peripheral pre-equatorial lens epithelium. The formation of the central disc is unclear, and it is not clinically present in about 20% of patients. In the other two zones, XFM initially consists of an even coating but is scraped by the iris border during routine dilation and constriction of the

**Fig. 10.13.1 Deposition of Exfoliation Material (XFM) Deposition on the Anterior Lens Capsule.** (A) Early in the disease, clefts form in the XFM as a result of iris rubbing over the lens. (B) In the mature phase, a central disc of XFM is seen with a relatively clear intermediate zone as a result of iris chaffing and a peripheral zone of granular deposits.

**Fig. 10.13.2** Iris pigment being released from ruptured cells of the pigment ruff during pupillary dilation.

iris. This results in the appearance of clefts in the material beginning at the site at which the iris touches the lens and continuing until this zone is denuded of XFM. At the same time, the XFM on the lens acts like sandpaper, causing rupture of iris pigment epithelial cells at the ruff and surrounding sphincter region, with concomitant pigment dispersion into the anterior chamber, leading to iris transillumination defects, loss of the ruff, and trabecular hyperpigmentation (Figs. 10.13.2 and 10.13.3).<sup>2,8-10</sup>

**Fig 10.13.3** Classic angle features of exfoliation syndrome showing irregular moderately dense pigmentation of the trabecular meshwork, pigment on Schwalbe's line, and a Sampaolesi's line

**Fig 10.13.4** Exfoliation material on vitreous strands in a patient with a ruptured posterior capsule.

An early sign of XFS is the development of radial, nongranular striae in the middle third of the lens capsule behind the iris (pregranular exfoliation). XFM can be identified on the ciliary body, zonules, corneal endothelium, and the angle. In patients with pseudo-phakia or aphakia, XFM on these structures and on vitreous strands (Fig. 10.13.4) often helps confirm the diagnosis. Because of the zonular fragmentation and instability inherent in this syndrome,<sup>17</sup> patients occasionally demonstrate phacodonesis or frank subluxation or dislocation of the natural or implanted lens (Fig. 10.13.5). XFS is the most common cause of subluxed intraocular lenses (IOLs).<sup>18</sup> Capsular phimosis may be a precursor to impending IOL subluxation.

Increased pigmentation in the angle is characteristic and may also occasionally be found on the corneal endothelium. XFS has been associated with nonguttate endothelial loss and subsequent corneal decompensation. Peripupillary iris transillumination defects (TIDs) are common, as opposed to the midperipheral radial TIDs of pigment dispersion syndrome (PDS). The angle deposition of pigment is often patchy and unevenly distributed in XFS, contrasting with the homogeneous dense angle pigment seen in PDS. A Sampaolesi's line, most often in the inferior angle, is frequently seen. Other suggestive signs are atrophy of the iris sphincter, poor dilation of the iris, anisocoria, a ground-glass appearance of the lens capsule, and heterochromia, in which the more involved side is lighter.

Pigment dispersion after pupillary dilation may be profuse. Marked IOP increases can occur, and IOP should be measured routinely in all patients after dilation. It should be stressed that all patients should be examined for pigment in the anterior chamber and XFM on the lens after dilation, as this is the only way to make the diagnosis, and failure to do this has led to marked underdiagnosis in the past. Dispersed pigment in the anterior chamber should prompt a careful search for XFM on the lens. Additionally, if pigment liberation is profuse, IOP should be checked an hour later. In patients known to have XFS and an IOP rise after dilation, apraclonidine or brimonidine given prior to dilation can ameliorate this condition.

**Fig 10.13.5** Spontaneously dislocated lens with only fragments of the zonules remaining.

Cataracts are etiologically related to XFS, virtually always being in the same eye when clinically unilateral. Antioxidant activity is reduced in the aqueous humor. Ischemia and oxidative damage correlate with the severity of IOP and glaucoma.<sup>19</sup> Zonules are fragmented and degenerated, contributing to an increased rate of complications at the time of cataract surgery.<sup>17</sup> Zonular laxity, allowing thickening, and anterior movement of the lens, combined with sphincter muscle fibrosis, iris stiffness, and cataract formation are a prominent cause of angle closure.<sup>9</sup> Other reported ocular associations include retinal vein occlusion, ocular surface disease, and macular degeneration.<sup>20</sup>

## GLAUCOMA IN EXFOLIATION SYNDROME

XFG is defined as glaucomatous optic neuropathy in patients with XFS. Blockage of aqueous outflow occurs by a combination of pigment and XFM in the intertrabecular spaces, juxtacanalicular meshwork, and beneath the endothelium of Schlemm's canal. Patients with XFS should be considered glaucoma suspects and monitored at least yearly, with a complete ophthalmic examination, IOP, visual field testing, and nerve fiber layer quantification, and more frequently if there is concern for or evidence of significant disease. Of the patients with XFS, 30%–40% eventually develop glaucoma.<sup>10</sup> XFS is more aggressive than POAG, and failure of medical treatment is more common. In some patients, the condition may have been stable for years but may get out of control and require further intervention.

Medical management of XFG is similar to that of POAG and consists of the use of all current classes of IOP-lowering pharmaceuticals. Prostaglandin analogues are those most frequently initially used. Pilocarpine increases trabecular outflow, which is beneficial in eyes with XFS. Not only does it lower IOP but should slow the progression of the disease by limiting pupillary movement. Unfortunately, pilocarpine has almost disappeared from use in glaucoma on the basis that it is considered a four-times-daily drug; because many patients have nuclear sclerosis, miotics may cause dim vision and long-term use may lead to the development of posterior synechiae. However, we have found that 2% pilocarpine at bedtime can provide sufficient limitation of pupillary mobility without causing these side effects. It produces a 3-mm nonreactive pupil, preventing the liberation of XFM and pigment by eliminating iridolenticular friction, and buildup of granular XMF at the pupillary border and on the center of the lens often occurs. Miotics may also exacerbate pupillary block, but generally not at this low dose. Conversely, if the angle is shallow as a result of zonular laxity, anticholinergic agents often paradoxically deepen the angle in XFS by tightening the cilio–zonular complex.

Argon or selective laser trabeculoplasty can be performed in XFS if the angle is open enough to allow laser application. Argon laser trabeculoplasty has been reported to have a higher success rate in XFS than in POAG and therefore is often used earlier in the management of XFS cases. Selective laser trabeculoplasty has been reported equally or less effective but can be attempted prior to argon treatment because it can be repeated.

If IOP is not adequately controlled with medical or laser treatment, surgical intervention should be considered. The results of trabeculectomy

are favorable, with no significant difference in the postoperative complication rate than in POAG. Newer and less invasive procedures, such as Trabectome or trabeculotomy have shown promise in XFG because they can eliminate trabecular blockage. Newer microinvasive glaucoma surgery procedures, such as XEN or CyPass, should equal their effect in POAG.<sup>21,22</sup>

Combined cataract and glaucoma surgery is common in patients with XFS, and several important considerations must be made in these cases. First, the zonular attachments in XFS are weakened and formerly this resulted in a 5–7 times greater incidence of lens subluxation, zonular dialysis, and vitreous loss. This has been significantly reduced by improved techniques of phacoemulsification and the use of iris and anterior capsular hooks, when necessary. Poor dilation is the single most important predictor for vitreous loss in cataract surgery among these patients. Capsular tension rings (CTRs) may be useful in decreasing zonular and capsular instability, as well as for improving IOL centration and decreasing capsular phimosis. Spontaneous dislocation of the capsular bag and its IOL has been reported with increasing frequency, and it is not yet known whether a CTR will prevent this late postoperative complication. In some cases, it may be necessary to place the IOL into the ciliary sulcus, preferably with optic capture within the capsule. Profound capsular instability may necessitate suture fixation of the lens to the iris or sclera. Other observations made in eyes with XFS include a greater risk for perioperative IOP spikes, posterior synechiae formation, and cellular precipitates on the IOL.

If the lens is unstable, it may be best to perform supracapsular phacoemulsification by aggressive hydrodissection of the lens from the capsular bag. A pars plana approach may be considered if the lens appears to be very unstable. Nonetheless, with a gentle and methodical surgical technique, the results of cataract surgery in patients with XFS can be quite good. If XFG is well controlled and there is no evidence of advanced visual field or nerve damage, clear cornea cataract surgery alone can produce improved IOP control.

With the use of modern surgical equipment and techniques, successful outcomes for the management of cataract and glaucoma in patients with XFS are increasing. Future research will pave the way for a better understanding of the pathogenesis and management of this disease.

## SYSTEMIC MANIFESTATIONS

XFS is associated with deposition of abnormal fibrillary material on both ocular and nonocular tissues. The first studies by Streeten and Schlötzer-Schrehardt in 1992 revealed XFM-like material in the heart, lungs, liver, kidneys, and meninges, closely associated with connective tissue, vascular wall cells, and muscle cells.<sup>10</sup> The most common systemic association of XFS is with ischemic disease, reflected in cardiovascular abnormalities and oxidative damage. It has been associated with cerebrovascular and cardiovascular disease, including hypertension, angina, coronary artery disease, arterial endothelial dysfunction, aortic aneurysm, and renal artery stenosis.<sup>23–26</sup>

More recently, it has been associated with elastic tissue disorders, specifically chronic obstructive pulmonary disease, inguinal hernia, and pelvic organ prolapse. Associated hearing loss has been strongly associated with XFS.<sup>27</sup> This is truly a protean disease. Nevertheless, there has been no report of increased mortality in patients with XFS. The role of homocysteine and folic acid in etiology has yet to be elucidated.

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis for XFS includes:

- Pigment dispersion syndrome.
- Capsular delamination (true exfoliation).
- Primary amyloidosis.

PDS is more often clinically bilateral, is more common in young men with myopia than in young women, and displays characteristic TIDs and uniform angle pigmentation. True exfoliation is a splitting of the anterior lens capsule without deposition of XFS material. It can occur on rare occasions secondary to heat, trauma, irradiation, or inflammation. Another rare condition that may produce fibrillar material deposition on the lens surface, different from XFM, is primary familial amyloidosis. Most commonly, XFG is misdiagnosed as POAG because of failure to recognize the characteristic clinical signs. XFS may also be confused with iritis if the material deposited on the corneal endothelium is confused with keratic precipitates (Fig. 10.13.6).

**Fig 10.13.6** Exfoliation material on the cornea mimicking keratic precipitates.

# Pigmentary Glaucoma

Andrew M. Williams, Kelly W. Muir

# 10.14

**Definition:** A form of open-angle glaucoma characterized by dispersion of pigment granules from the iris pigment epithelium, with deposition throughout the anterior segment, including the trabecular meshwork.

## Key Features

- Pigment deposition on the corneal endothelium (Krukenberg's spindle).
- Midperipheral, spoke-like iris transillumination defects.
- Heavy, homogeneous pigmentation of the trabecular meshwork.

## Associated Features

- Presence of key features but without glaucoma is called *pigment dispersion syndrome* (PDS).
- Patients with PDS have a 35%–50% lifetime risk of progressing to pigmentary glaucoma.
- Typical patient is a young man with myopia.
- Predominantly in white patients.
- "Reverse" pupillary block mechanism.

## INTRODUCTION

In 1949, Sugar and Barbour described a patient with pigment dispersion in the anterior chamber and glaucoma and coined the term *pigmentary glaucoma*.<sup>1</sup> Although once thought to be a rare form of open-angle glaucoma, it has been estimated to account for 0.5%–5% of the glaucoma population in the United States.<sup>2</sup> A several-fold larger number of individuals have the typical pigment dispersion without glaucoma, which is referred to as *pigment dispersion syndrome* (PDS).

The mechanism of the pigment dispersion (Box 10.14.1) was suggested by Campbell in 1979 as friction between the iris pigment epithelium and packets of lens zonules, which results from a posterior bowing of the peripheral iris.<sup>3</sup> This iris configuration is seen most commonly in young men with myopia and is felt to result from a reverse pupillary block.<sup>4</sup> The probability of converting from PDS to pigmentary glaucoma has been estimated at about 15% at 15 years,<sup>5</sup> or 35%–50% over the course of a lifetime.<sup>6–9</sup>

### BOX 10.14.1 Stages of Pigmentary Glaucoma

- Pigment dispersion syndrome (PDS)
  - Active or inactive pigment dispersion with stable IOP
- Pigmentary glaucoma (develops in 35%–50% of PDS cases)
  - Clinically reversible stage:
    - Pigment accumulation in the trabecular meshwork
    - Trabecular endothelial phagocytosis
    - Endothelial cell autolysis and migration
  - Clinically irreversible stage:
    - Trabecular meshwork denudation and degeneration
    - Trabecular meshwork collapse and sclerosis

From Farrar SM, Shields MB. Current concepts in pigmentary glaucoma. *Surv Ophthalmol* 1993;37:233–52.

## EPIDEMIOLOGY AND PATHOGENESIS

The prevalence of PDS is uncertain, as variable degrees of phenotypic expression may lead to underdiagnosis. Estimates range from 10–100 per 100 000, with one group finding a rate as high as 2% in a population undergoing glaucoma screening.<sup>10</sup> Although the PDS is found in roughly equal numbers of men and women, pigmentary glaucoma is more common in men, who have a 3:1 predominance. The glaucoma also tends to occur earlier in men (age at onset 35 years) than in women (46 years), with a tendency in both genders for the condition to decrease in severity or disappear by the sixth to seventh decades of life.<sup>7,11</sup> Patients usually have myopia, and there is a strong preponderance of white patients.

PDS has a complex genetic pattern. One study of four families linked the condition to the long arm of chromosome 7 (7q35–q36) with autosomal dominant inheritance.<sup>12</sup> Although other genetic loci have been evaluated, no single causal gene has been identified. Research in mice has established causal mutations in melanosomal proteins, but the inheritance of PDS likely involves multiple genes that have variable expressivity and penetrance.<sup>13,14</sup>

The configuration of the eye is believed to be responsible for the forces that lead to the iridozonular friction and pigment dispersion. The eyes are larger than average in size, explaining the preponderance of men and those with myopia, and the anterior chamber is deep, which may explain the spontaneous improvement in older patients, as lens changes lead to a shallowing of the chamber. Other anatomical features associated with pigment dispersion are a flatter corneal curvature than in age-matched controls with myopia,<sup>15</sup> a more posterior insertion of the iris into the ciliary body,<sup>16</sup> and a relatively larger iris.<sup>17</sup>

In addition to the above-noted anatomical features, which favor iridozonular friction, histopathological observations of the iris of patients with PDS and pigmentary glaucoma have revealed focal atrophy, hypopigmentation, and apparent delayed melanogenesis of the iris pigment epithelium.<sup>18</sup> It may be, therefore, that both the mechanical iridozonular friction and a developmental abnormality of the iris pigment epithelium are necessary to produce the liberation of pigment granules in these patients.

The concept of reverse pupillary block is critical to an understanding of the mechanisms that lead to pigmentary glaucoma. The configuration of the eye in these patients appears to favor a "pumping" action of the iris, in which eye movement, as with blinking, causes the peripheral iris to act as a bellows in forcing aqueous from the posterior to the anterior chamber. This results in a reverse pressure gradient, that is, higher in the anterior than posterior chamber. The iris then acts as a one-way valve against the lens, preventing aqueous from returning to the posterior chamber. The increased pressure in the anterior chamber leads to posterior bowing of the midperipheral iris and consequently to the rubbing of the iris pigment epithelium against packets of lens zonules, with liberation of pigment granules into the aqueous. Once released into the aqueous, some of the pigment granules then lodge in the trabecular meshwork and obstruct aqueous outflow, resulting in elevated intraocular pressure (IOP).<sup>19</sup> Support for the concept of reverse pupillary block is seen in ultrasound biomicroscopy studies, in which prevention of blinking eliminates the posterior bowing.<sup>20</sup>

Histopathological examinations show that the trabecular endothelial cells engulf the pigment, which results in cell injury and death from phagocytic overload.<sup>21</sup> Macrophages carry off the pigment and debris, leaving the denuded collagen beams to collapse and fuse, with obliteration of the outflow channels. This may explain why treatments directed at increasing trabecular outflow, such as laser trabeculoplasty, are more effective in the earlier stages of pigmentary glaucoma than later in the course.

**Fig. 10.14.1 Transillumination Defects.** The radial, midperipheral, spoke-like iris transillumination defects, typical of patients with pigmentary glaucoma, correspond anatomically to packets of lens zonules.

**Fig. 10.14.2 Krukenberg's Spindle.** Vertical, spindle-shaped deposition on central corneal endothelium in patient with pigmentary glaucoma.

## OCULAR MANIFESTATIONS

Contact between the iris and packets of lens zonules leads to characteristic midperipheral, spoke-like iris transillumination defects. This typically appears first in the inferior quadrant, but may be seen for 360° in advanced cases (Fig. 10.14.1). With elimination of the iridozonular friction, as a result of either treatment or age, the transillumination defects gradually fill in and disappear. Characteristically, the dispersed pigment granules deposit on ocular structures in the anterior segment. One of the most common manifestations is a vertical, spindle-shaped deposition on the central corneal endothelium, referred to as *Krukenberg's spindle* (Fig. 10.14.2). Pigment granules may also accumulate in the radial and circumferential iris ridges. But the most classic finding, and the final mechanism of IOP elevation, is the dense, homogeneous pigmentation of the trabecular meshwork (Fig. 10.14.3).

## DIFFERENTIAL DIAGNOSIS

There are several additional forms of glaucoma that may have variable amounts of pigment dispersion in the anterior chamber and which must be distinguished from pigmentary glaucoma, including *pseudo-exfoliation syndrome*, glaucoma in pseudo-phakia, in which the iris rubs against the

**Fig. 10.14.3 Gonioscopic Appearance in Pigmentary Glaucoma.** A wide, open angle with heavy, homogeneous trabecular meshwork pigmentation is a consistent feature of pigmentary glaucoma.

optic or haptic of a posterior chamber intraocular lens, some forms of uveitis, trauma, ocular melanosis and melanoma, and chronic open-angle glaucoma with increased pigment dispersion.

## TREATMENT

Treatment options for pigmentary glaucoma include medical management, laser therapy, and surgery. Initial treatment is typically medical. In particular, prostaglandins have been found to lower IOP more significantly than beta-blockers in patients with pigmentary glaucoma and are therefore usually considered first-line therapy.<sup>22</sup>

Selective laser trabeculoplasty (SLT) is effective in treating pigmentary glaucoma, especially in the early stages of the disease. Interestingly, one recent study suggests that its long-term efficacy is less certain, with an 85% success rate at 12 months but only a 14% success rate at 48 months after treatment.<sup>23</sup> Additionally, caution must be used with SLT because patients with heavily pigmented trabecular meshwork may have significant post-laser treatment IOP elevations.<sup>24</sup> Treating 180° versus 360° of the meshwork and/or using lower power may reduce the risk of post-laser treatment IOP elevation.

The use of laser peripheral iridectomy (LPI) in the setting of pigment dispersion with open angles is controversial. Although LPI does appear to flatten the iris configuration, several studies have found that this has no benefit in reducing disease progression compared with control groups,<sup>25,26</sup> perhaps as a result of pigment liberation from the iridectomy. Interestingly, one study did find support for LPI for eyes with PDS that are at high-risk for converting to pigmentary glaucoma.<sup>27</sup> A 2016 Cochrane review of five randomized-controlled trials found insufficient evidence to make a recommendation for or against LPI in PDS or pigmentary glaucoma.<sup>28</sup>

Incisional surgery is considered when more conservative measures fail to control the disease. Trabeculectomy is an effective, well-established procedure in this population.<sup>29</sup> Most recently, minimally invasive glaucoma surgery (MIGS) have been examined as a treatment modality for pigmentary glaucoma. Early data suggest that ab interno trabeculectomy may be similarly effective for pigmentary glaucoma compared with primary open-angle glaucoma.<sup>30</sup> In contrast, trabecular microbypass stent failed in all three included cases of pigmentary glaucoma in a recent retrospective study, all of whom experienced significant postoperative IOP elevation and required trabeculectomy.<sup>31</sup> With paucity of available data, it is unclear at present what role MIGS has in management of pigmentary glaucoma.

## COURSE AND OUTCOME

Individuals with PDS must be monitored closely as glaucoma suspects because of the risk of conversion to pigmentary glaucoma, which can have a relatively aggressive nature. Although the disease does have a tendency

to “burn out” in later life, the stakes are high in the patient with pigmentary glaucoma because of its early onset. Therefore, aggressive treatment is often required to ensure that these individuals will get through the active decades of the glaucoma with their sight intact.

# Neovascular Glaucoma

Malik Y. Kahook

10.15

**Definition:** A secondary glaucoma resulting from neovascularization of the anterior segment, including the iris and angle, often associated with and/or secondary to retinal ischemia.

**Key Features**

- Neovascularization of the iris, angle, and anterior chamber.
- Elevated intraocular pressure.
- Peripheral anterior synechiae.

**Associated Features**

- Decreased vision.
- Ectropion uveae.
- Anterior chamber inflammation.
- Cupping of the optic nerve.
- Corneal edema, depending on acuteness.
- Conjunctival congestion.
- Retinal disease with ischemia, inflammation, or tumor.

**INTRODUCTION**

Neovascular glaucoma (NVG) occurs when new vessels proliferate onto the iris surface and over the anterior chamber angle structures, namely, the trabecular meshwork. Retinal ischemia with retinal capillary nonperfusion and subsequent secretion of vasoproliferative factors are the events that lead to neovascularization and glaucoma in most cases. The evolution of NVG usually follows an ordered sequence, beginning with new vessel formation and ending with fibrovascular membranes migrating over the drainage angle, potentially leading to end-stage glaucoma. There is a high likelihood of profound vision loss once intraocular pressure (IOP) increases, making early diagnosis key to preserving ocular function. Medications, laser treatment, and incisional surgery have been the mainstay of treatment. Recently, treatment modalities targeting the vasoproliferative factors directly have emerged, potentially improving outcomes.

**EPIDEMIOLOGY AND PATHOGENESIS**

Coats described the occurrence of iris neovascularization in connection with central retinal vein obstruction (CRVO) in 1906.<sup>1</sup> Weiss et al. coined the term *neovascular glaucoma* in 1963, basing the diagnosis on the presence of new vessels on the iris leading to increased IOP.<sup>2</sup> Diabetic retinopathy and CRVO are the most common pathological processes involved in the development of ocular neovascularization (Box 10.15.1). Thirty-six percent of all cases of NVG arise from CRVO, 32% from proliferative diabetic retinopathy, and 13% from carotid artery occlusive disease.<sup>3</sup> The common denominator in all of these diseases is ocular tissue hypoxia.

The concept of an angiogenic factor stimulating new vessel proliferation as a consequence of hypoxia has long been theorized. Recent advances in molecular biology identified vascular endothelial growth factor (VEGF) as a leading protein involved in the neovascular cascade. Tolentino et al. showed that injection of recombinant human VEGF is sufficient to produce neovascularization in a nonhuman primate model.<sup>4</sup> Tripathi et al. found elevated VEGF levels in the aqueous humor of patients with neovascular glaucoma.<sup>5</sup> Sample analysis detected VEGF in all 12 samples from patients with NVG, 15 of 28 of patients with primary open-angle glaucoma, and 4 of 20 aqueous humor samples from patients with cataract. Mean VEGF concentration in the aqueous humor of patients with NVG was 40 and 113

**BOX 10.15.1 Causes of Iris Neovascularization**

**Retinal Ischemia**

- Diabetic retinopathy
- Central retinal vein occlusion
- Central retinal artery occlusion
- Retinal detachment
- Sick cell retinopathy
- Retinoschisis
- Carotid artery occlusion

**Inflammatory**

- Chronic uveitis
- Endophthalmitis
- Vogt–Koyanagi–Harada syndrome
- Sympathetic ophthalmia

**Tumors**

- Choroidal/iris melanoma
- Ocular lymphoma
- Retinoblastoma

**Irradiation**

- External beam radiation
- Charged particle therapy
- Plaque therapy

**BOX 10.15.2 Stages of Neovascular Glaucoma**

**Stage I: Rubeosis Iridis**

- Normal IOP
- NVI with or without NVA
- Vascular tufts at pupillary margin

**Stage II: Open-Angle Glaucoma**

- Elevated IOP
- Increased NVI and NVA
- No synechial angle closure

**Stage III: Angle-Closure Glaucoma**

- Elevated IOP
- Reduced visual acuity
- Synechial angle closure

IOP, intraocular pressure; NVA, neovascularization of the angle; NVI, neovascularization of the iris.

times higher than that of patients with POAG and cataract, respectively. Recently, anti-VEGF medications have been shown to dramatically reduce ocular neovascularization when injected in the vitreous of patients with macular degeneration and NVG.<sup>6,7</sup>

Although ischemia is believed to be a primary instigator of angiogenesis, other factors play a role in abnormal vessel formation. Inflammation and hypoxia often coexist in the microenvironment leading to new vessel formation. These links remain incompletely understood and only recently have they been partially elucidated. Inflammatory mediators, such as angiopoietin-1 and angiopoietin-2, are now known to play a role in new vessel formation and remodeling, along with their role in inflammation.<sup>8</sup> Furthermore, intravitreal triamcinolone, a potent anti-inflammatory agent, has shown modest efficacy in decreasing iris neovascularization.<sup>9</sup> Theoretically, corticosteroids decrease neovascularization by interrupting the inflammatory cascade that contributes to the neovascular drive.

**OCULAR MANIFESTATIONS**

Neovascular glaucoma can be divided into three stages (Box 10.15.2). Stage 1 consists of vascular proliferation at the pupillary margin. Neovascularization of the iris may be difficult to detect at this point. Slit-lamp biomicroscopy reveals fine, tortuous, randomly oriented tufts of vessels on the

**Fig. 10.15.1 Neovascularization of the Iris.** Note the florid neovascular proliferation at the pupillary margin, which grows in random orientation on the iris surface.

**Fig. 10.15.2 Neovascularization of the Angle.** Gonioscopic view of new vessels that cover the trabecular meshwork and impart a characteristic red flush.

surface of the iris, near the pupillary margin. These tufts may be obscured in dark irides and more obvious in lighter irides. Neovascularization characteristically progresses from the pupillary margin toward the angle (Fig. 10.15.1) of undilated pupils, but angle neovascularization in the absence of pupillary involvement may occur. Repeated gonioscopy is indicated in eyes at high risk for the development of NVG. As vascular proliferation develops, biomicroscopy of the anterior chamber shows cells and flare. Gonioscopy reveals new vessels that grow from the circumferential artery of the ciliary body onto the surface of the iris and onto the surface of the wall of the angle.

The vessels cross the angle recess and grow forward over the ciliary body band and scleral spur onto the trabecular meshwork, which imparts a characteristic red flush (Fig. 10.15.2). Early in the course of anterior segment neovascularization the IOP often is normal. The new blood vessels arborize to form a fibrovascular membrane (invisible on gonioscopy) that gives rise to a secondary open-angle glaucoma representing the second stage of NVG. Stage II of NVG is characterized by contraction of the fibrovascular membrane, which pulls the peripheral iris over the trabecular meshwork and results in variable degrees of synechial angle closure. Ectropion uveae and hyphema occur frequently. Ectropion uveae results from radial traction along the surface of the iris, which pulls the posterior pigmented layer of the iris around the pupillary margin onto the anterior iris surface. It is at this stage that patients may present with the dramatic onset of pain secondary to elevated IOP. Patients typically experience severely reduced visual acuity accompanied by corneal edema and anterior chamber inflammation. Stage III findings are similar to stage II findings, with the exception that synechial angle closure is present.

## DIAGNOSIS

The medical history is crucial in evaluating patients for the development of NVG. Diabetes mellitus, hypertension, arteriosclerosis, and a previous history of vision loss indicative of CRVO, central retinal artery obstruction (CRAO), or retinal detachment are important. Recent ocular surgery may increase the risk in predisposed individuals. It is imperative that a

### BOX 10.15.3 Differential Diagnosis of Neovascular Glaucoma

- Uveitic glaucoma
- Acute angle-closure glaucoma
- Chronic angle-closure glaucoma
- Iridocorneal endothelial syndrome
- Fuchs' heterochromic iridocyclitis

posterior segment examination be performed in all patients to identify concomitant retinal disease. The diagnosis of NVG is made on the basis of clinical examination findings. Careful slit-lamp and gonioscopic examinations are usually sufficient to make the diagnosis. An undilated pupil is helpful. The goal is to establish the diagnosis well before angle structures become involved and elevated IOP or synechial angle closure occurs.

Involvement of the anterior chamber angle sometimes occurs before the appearance of neovascularization of the iris. These vessels typically run on the iris surface, follow a nonradial course, and may cross the scleral spur. Thus, gonioscopy must be performed on every patient at risk for the development of NVG. In most instances, however, small tufts of neovascularization are noted first at the pupillary margin. This tendency for initial involvement of the pupillary margin appears to result from aqueous flow dynamics, whereby angiogenic factors produced in the posterior segment have the most contact with the pupillary margin.

Occasionally, early neovascularization may be missed when the new vessels are fine and thin, the iris is darkly pigmented, or pressure from the gonioscopy lens reduces the caliber of the new vessels and renders them clinically unapparent. Frequent follow-up of patients at high risk for NVG enables early detection of new vessels in difficult cases. Fluorescein angiography (FA) of the iris may be used to demonstrate the presence of new vessels before they become visible clinically with slit-lamp biomicroscopy. FA of the retinal circulation, if corneal clarity and pupillary dilation allows, is an important adjunct. Peripheral sweeps and wide field angiography are especially helpful in detecting peripheral retinal capillary nonperfusion as well as detecting posterior-segment neovascularization.

The b-wave to a-wave amplitude ratio of the bright-flash, dark-adapted electroretinography may help predict which eyes will develop NVG following CRVO.<sup>10</sup> This ratio was found to be less than 1.0 (average 0.84) in eyes that developed NVG after ischemic CRVO. In contrast, the b-wave to a-wave amplitude ratio was always greater than 1.0 in eyes that did not develop NVG following CRVO.

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis of NVG is summarized in Box 10.15.3. The diagnosis of NVG is often made easy by the appearance of iris neovascularization in the presence of retinal pathology. However, occasional cases are less obvious with subtle neovascularization and little or no visible retinal pathology. In these cases, the treating physician should be familiar with other disease processes infrequently linked to rubeosis iridis and high IOP. Uveitic glaucoma can mimic NVG with high pressure and dilated iris vessels. Fuchs' heterochromic iridocyclitis can present with high IOP and abnormal vessels in the anterior chamber angle. Finally, end-stage NVG can look identical to chronic angle-closure glaucoma with angle closure because of diffuse anterior synechiae.

## TREATMENT

The key to successful management of NVG is early diagnosis. Recognition of neovascularization of the iris is crucial so that preventive treatment can be initiated before the anterior chamber angle is closed by peripheral anterior synechiae. Once the florid, intractable final stage is established, the eye is likely blind, with very high IOP and painful bullous keratopathy. If the NVG is secondary to carotid artery or other systemic disease, it is important to evaluate and treat the primary systemic condition.

Panretinal photocoagulation (PRP) remains the first line of therapy in almost all cases of NVG. Prompt application of PRP has been shown to achieve regression of anterior and posterior segment neovascularization and to reduce the risk of developing neovascularization of the iris in eyes that have retinal vascular disease.<sup>11</sup> In the open-angle glaucoma stage and early angle-closure glaucoma stage, PRP may reverse or mitigate IOP elevation. For eyes that have advanced synechial angle closure of the anterior chamber with some potentially useful vision, PRP may eliminate

the stimulus for neovascularization, which prepares the eye for filtering surgery and the prevention of further visual loss.

Panretinal cryotherapy is an alternative to PRP in eyes that have cloudy media and in eyes for which complete PRP fails to halt the progression of neovascularization.<sup>12</sup> It is rarely employed, given its high rate of complications. Goniophotocoagulation may be used as an adjunct to PRP to reduce neovascularization in the angle before it is closed by synechiae, but generally the effects are only temporary.<sup>13</sup> The treatment of NVG is directed by the visual potential. Any usable vision, even 20/400 (6/120) or less in a monocular patient, is worth preserving.

The role of glaucoma filtering surgery in NVG is to prevent pressure-induced injury to the optic nerve and, theoretically, to improve vascular perfusion. Before glaucoma surgery, every attempt is made to reduce or eliminate the stimulus for angiogenesis using PRP. By allowing the maximal amount of time between PRP and glaucoma surgery, the risk of intraoperative and postoperative bleeding and severe intraocular inflammation is reduced. The importance of complete preoperative PRP to the success of glaucoma filtering surgery in patients who have NVG cannot be overstressed.

Of special importance is the use of intraoperative cautery to achieve hemostasis and to avoid bleeding. Direct cauterization of the peripheral iris before iridectomy may reduce the risk of bleeding. Variable success rates have been reported after conventional filtering surgery in patients who have NVG. Allen et al.<sup>14</sup> reported IOP control in 67% of patients who had NVG and underwent trabeculectomy or posterior lip sclerectomy after PRP. Tsai et al.<sup>15</sup> reported a high risk of long-term failure with 5-fluorouracil filtering surgery; 12 of 34 patients with NVG (35%) lost light perception vision, and eight patients (24%) developed phthisis bulbi over a 5-year follow-up period. Younger age ( $\leq 50$  years) and type I diabetes mellitus are significant risk factors for early surgical failure. Skuta et al.<sup>16</sup> described the use of mitomycin C with trabeculectomy in patients who had NVG.

Glaucoma drainage implants are also used for the primary surgical treatment of NVG. Seton procedures place the effective sclerostomy inside the anterior chamber away from the angle, which maintains a patent fistula between the anterior chamber and an equatorial bleb. Sidoti et al.<sup>17</sup> cited life-table success rates of 79% and 56% at 12 and 18 months, respectively, following Baerveldt glaucoma implantation surgery for NVG. Success was defined as a final IOP of 6–21 mm Hg (0.8–2.8 kilopascals [kPa]) without additional glaucoma surgery or devastating complications. Loss of light perception occurred in 31% of patients. Cox model regression survival analysis demonstrated young patient age and poorer preoperative visual acuity as significant predictors of surgical failure. Another study that evaluated the use of the single-plate Molteno valve implantation for NVG reported success rates of 62% at 1 year, 52.9% at 2 years, 43.1% at 3 years, 30.8% at 4 years, and 10.3% at 5 years; loss of light perception was seen in 29 of 60 eyes (48%), and phthisis bulbi developed in 11 eyes (18%).<sup>18</sup>

Noninvasive techniques are employed to achieve patient comfort if the eye has no visual potential. Topically administered corticosteroids and cycloplegics may relieve ocular discomfort. Topical beta-adrenergic blockers, alpha-adrenergic agonists, and carbonic anhydrase inhibitors may be used to reduce aqueous production. Miotic therapy is avoided because it may aggravate intraocular inflammation and pain. Once the anterior chamber angle is closed, medical therapy alone may not provide long-term IOP control, and surgical intervention becomes necessary. Cyclocryotherapy had been advocated in the treatment of elevated IOP in NVG. Although the IOP can be controlled in a high percentage of patients who undergo the procedure, the long-term visual outcome is dismal; loss of light perception occurs in 58.5% of patients. In addition, the high incidence of major complications, which include anterior segment necrosis and phthisis bulbi (34%), means that its use in eyes that have visual potential is limited.<sup>19</sup> Other modalities of therapy to control IOP include diode and neodymium:yttrium–aluminum–garnet transscleral cyclophotocoagulation. Schuman et al.<sup>20</sup> reported a 39% success rate using the latter in patients who had advanced NVG. As laser treatment has evolved, the standard cyclodestructive modality has become diode laser cyclophotocoagulation of the ciliary body. This technique is typically performed transsclerally with an 810 nm diode laser equipped with a semidisposable G-probe. The pain and inflammation of this procedure is typically less than that seen with prior, more destructive versions. More targeted techniques using an endoscope in the operating room setting have also been used to adequately lower IOP.<sup>21</sup>

In painful eyes that have poor visual potential, cycloablation, retrobulbar alcohol injection, and enucleation may help achieve comfort.

## COURSE AND OUTCOME

The natural course of NVG is uniformly one of complete loss of vision and the development of intractable, severe pain. The high degree of ocular morbidity and mortality in patients who have NVG emphasizes the severity of the underlying systemic conditions associated with diabetic retinopathy and CRVO, the main causes of this disorder. Usually, NVG occurs in patients burdened with serious systemic disease. Krupin et al.<sup>22</sup> and Mermoud et al.<sup>18</sup> cited mortality rates of 22% and 15% in patients who have NVG. Diabetes mellitus was the underlying cause of NVG in the majority of patients reported by the Diabetes Control and Complication Research Group,<sup>23</sup> which highlights the importance of effective blood sugar control in patients who have diabetic retinopathy. The risk of progression of mild diabetic retinopathy and the development of proliferative diabetic retinopathy is reduced to half in patients using effective blood sugar control.

NVG does not invariably follow the development of neovascularization of the iris. When such neovascularization is detected, it behooves the clinician to monitor patients carefully with repeated slit-lamp examinations and undilated gonioscopy. Neovascularization of the iris has been reported to develop in 50% of patients who have proliferative diabetic retinopathy and in 60% of those who have the ischemic type of CRVO. It is imperative that PRP be applied promptly to ischemic retina to eliminate the stimulus for further neovascularization.

Visual loss in NVG is common and may be attributed to a combination of causes, including severe ocular ischemia with progression of the underlying retinal disease, glaucomatous optic nerve damage, cataract formation, corneal decompensation, and phthisis bulbi. The most common cause of surgical failure in patients who have NVG is related to progression of the underlying retinal disease, not to uncontrolled IOP.<sup>15,17,22</sup> The ultimate solution for patients who have NVG lies in the development of new modalities of treatment designed to prevent the initiation of neovascularization. Murata et al.<sup>24</sup> recently showed that thiazolidinediones, a novel class of drugs that can be used to improve insulin resistance in type II diabetes, inhibit angiogenic responses to VEGF in vitro. Current research to develop pharmacological therapies targeted at the inhibition of angiogenic factors offers hope for the preservation of vision in patients at risk.

## EMERGING TREATMENTS

It is clear that the best way to treat NVG is to prevent it from occurring in the first place. Having failed to prevent its occurrence, NVG is best dealt with when diagnosed early and treated aggressively. Current therapeutic options, such as laser and incisional surgery, carry with them the high risk of loss of visual field or visual acuity and, in the case of drainage devices and trabeculectomy, a high risk of infection. Newer treatment modalities should offer more precise targeting of the angiogenic mediators.

Antiangiogenic medications are promising as new methods for treating NVG. Bevacizumab (Avastin, Genentech) has been investigated as a potential adjunct in the treatment of NVG.<sup>7</sup> VEGF is a potent mitogen specific for vascular endothelial cells and is upregulated under conditions of retinal ischemia and NVG.<sup>25,26</sup> A downregulation in the production of VEGF through the use of inhibitors should limit neovascularization in diseases that lead to retinal ischemia.<sup>27</sup> Multiple case series publications have highlighted the regression of neovascularization of both the iris and angle after injections of VEGF inhibitors.<sup>7,26–33</sup> Kahook et al.<sup>7</sup> described the case of a patient who was treated with the anti-VEGF bevacizumab after having failed IOP control with transscleral CPC and PRP. A rapid decrease in IOP was noted, and the patient experienced symptomatic improvement within 48 hours. Other similar case reports found matching results after use of bevacizumab for NVG.<sup>29,30</sup>

Iliev et al.<sup>31</sup> described the use of intravitreal bevacizumab (IVB; 1.25 mg/0.05 mL) in a series of six consecutive patients with NVI and refractory NVG. They noted marked regression of anterior segment neovascularization and rapid relief of symptoms. IOP was significantly reduced in three patients, and in the remaining three patients, IOP was controlled after the addition of CPC and PRP. Oshima et al.<sup>32</sup> described IVB treatment of seven eyes with NVI caused by PDR and reported that NVI regressed within 1 week. With the use of iris FA, Grisanti et al.<sup>33</sup> studied the effects of IVB on NVI and noted a decrease in iris FA leakage as early as one day after injection.

Gheith et al.<sup>34</sup> presented a case series of six patients with NVG, each of whom received 1.25 mg/0.05 mL IVB, followed by PRP 1 week later. All patients had a complete regression of iris and angle neovascularization. Those authors noted that topical medications failed to control IOP in the patients who developed peripheral anterior synechiae, and they also

highlighted the need for continued monitoring of patients because of the long-term risk of recurrence of neovascularization seen in some patients. It should be noted that Bakri et al.<sup>35</sup> found the vitreous half-life of 1.25 mg IVB was 4.32 days in a rabbit eye. Recurrence of neovascularization is to be expected if the hypoxic drive remains in place from an ischemic retina. It is clear within our university based practice that anti-VEGF injections (bevacizumab, ranibizumab, or aflibercept) are becoming a standard of care for patients presenting with NVG and have improved comfort and visual outcomes when combined with PRP and CPC and/or prior to performing incisional surgery, such as trabeculectomy and glaucoma drainage device implantation.

# Inflammatory and Corticosteroid-Induced Glaucoma

10.16

Ridia Lim, Ivan Goldberg

**Definition:** Characteristic glaucomatous optic neuropathy associated with ocular inflammation and/or exposure to corticosteroids.

## Key Features

- Optic disc pallor and cupping and nerve fiber bundle perimetric defect(s), with evidence of inflammation involving one or more ocular tissues and/or past or continuing exposure to corticosteroids.
- Pre-existing glaucoma or a tendency to angle-closure may pre-exist and may contribute to pathophysiology.

## Associated Features

- Variably raised and/or fluctuating intraocular pressure (IOP).
- Mechanisms for IOP rise may vary over time and require continuous reassessment to focus treatment effectively.
- Use of corticosteroids may lead to IOP rise; treatments that exacerbate inflammation (miotics) should be avoided.
- Specific treatment for the cause of any uveitis is important. Nonspecific treatments of uveitis include corticosteroids, nonsteroidal anti-inflammatory drugs, immunosuppressives, and newer biological agents.
- Inflammatory glaucomas should be treated with ocular hypotensive medications (primarily aqueous suppressants), laser therapies, and augmented filtering surgery.
- Hypotony is a risk with drainage surgery, especially if there has been previous cyclodestruction.

## INTRODUCTION

Ocular inflammation and/or corticosteroid use can cause glaucomatous damage by elevating intraocular pressure (IOP) and/or by ischemia or infiltration of the optic nerve head.

To be effective, management needs to include precise detection of inflammation, treatment of the inflammation *and* its underlying cause (if possible), elucidation of the mechanism(s) of any IOP elevation, and its effective control.

Symptoms and signs may vary from marked to none; clinical course may be acute, subacute, unpredictably relapsing, or chronic. Management of the inflammation and any glaucoma is often challenging, especially as the mechanism(s) for raised IOP may change. This demands ongoing re-evaluation of mechanism(s) raising IOP and changes to treatment.

Raised IOP complicates about 20% of clinic-based uveitis cases; about 40% of these later have abnormal perimetry.<sup>1</sup> It is more common with anterior uveitides than with intermediate or posterior uveitides.

## PATHOPHYSIOLOGY

The relationship between IOP and inflammation is complex. IOP depends on the comparative rates of aqueous production and outflow (trabecular and uveoscleral). All of these, as well as aqueous circulation, can be altered by inflammation, by its effects on the ocular tissues involved, and by treatment, particularly corticosteroids. To identify the different processes that may change over time, repeated careful history and examination are required.

### BOX 10.16.1 Possible Causes of Raised Intraocular Pressure

- Secondary open-angle glaucoma
  - Trabecular meshwork obstruction
  - Schlemm's canal and episcleral venous outflow obstruction
  - Corticosteroid-induced elevation of intraocular pressure
  - Permanent, direct trabecular meshwork tissue damage
  - Post-trabecular outflow damage
  - Hypersecretion
- Pre-existing primary open-angle glaucoma
- Secondary angle-closure glaucoma
  - Peripheral anterior synechiae
  - Posterior synechiae
- Pre-existing disposition to primary angle-closure glaucoma
- Combined-mechanism glaucoma

Development of glaucomatous optic neuropathy depends on disease chronicity and susceptibility to corticosteroids, as well as to dose and duration, patient age, and optic nerve susceptibility to damage. Some eyes have multimechanism glaucoma. Although elevated IOP is a risk factor for uveitic glaucoma, IOP may not be elevated, and raised IOP (uveitic “ocular hypertension”) does not universally lead to glaucoma.

## MECHANISMS OF ELEVATED IOP

See Box 10.16.1.

### Secondary Open-Angle Glaucoma

*Trabecular meshwork obstruction* is the most common mechanism<sup>2</sup> and may occur after the following:

- White blood cell accumulation (macrophages and activated T lymphocytes) or their aggregations—seen gonioscopically as small pale yellow or gray precipitates or later as fine peripheral anterior synechiae and angle-closure glaucoma.
- Inflammatory debris, such as proteins, fibrin or even normal serum components after blood–aqueous barrier (BAB) breakdown—IOP may rise from increased aqueous viscosity. Altered vascular permeability may persist indefinitely, with a subtle aqueous flare-up being the clinical clue. This may predispose to recurrent inflammations by increasing intraocular concentrations of such substances as prostaglandins.
- Rarely, other solid components contribute to the blockage, for example, in Schwartz's syndrome (rhegmatogenous retinal detachment, uveitis and glaucoma, rod outer segments can block trabeculum).<sup>3</sup>
- Swelling of trabecular lamellae and endothelial cells with narrowing of trabecular pores and dysfunction.
- Overwhelming the trabecular endothelial phagocytic and pathway-clearing processes by a severe inflammation.
- If trabecular endothelial cell loss or damage becomes irreversible, permanent reduction in conventional outflow ensues.
- Direct trabecular damage from keratitis or the toxic effects of corneal stromal destruction. Keratitis without uveitis rarely elevates IOP.

These various mechanisms may potentiate one another.

Schlemm's canal and episcleral venous outflow obstruction can be caused by similar physical and chemical means or by raised episcleral venous pressure—particularly with scleritis, episcleritis, and keratitis.

Corticosteroids induce IOP elevation in susceptible patients by reducing trabecular outflow facility through changes to the mechanical structure of the trabecular meshwork, extracellular matrix trabecular deposits, and reduction of trabecular endothelial functional and phagocytic activity.<sup>4</sup> This is possible with topical, other local (dermal or inhalational), depot (subconjunctival, sub-Tenon's, intravitreal), or systemic corticosteroids. Following 4–6 weeks of topical corticosteroids, in about 5% of patients IOP will rise by more than 16 mm Hg and in 30%, by 6–15 mm Hg.<sup>5,6</sup> In a minority, IOP rise can be faster and to a greater extent; risk factors for this include primary open-angle glaucoma (POAG), family history of glaucoma, very young or older age, diabetes, connective tissue disease, and myopia.<sup>7</sup> Ninety-two percent of patients with POAG are high corticosteroid responders, with 19% of their children also being high responders.<sup>6</sup> Intravitreal triamcinolone acetonide can increase IOP for months. A 20-mg dose increased IOP above 21 mm Hg in 40% of individuals for up to 9 months; of these, 1% required trabeculectomy.<sup>8</sup> More than 50% of children age less than 10 years respond to dexamethasone.<sup>9</sup> Within 2 years of implanting the intravitreal Retisert implant (0.59 mg fluocinolone acetonide; Bausch & Lomb), which acts for more than 30 months, 60% required IOP-lowering medications, and 32% needed filtering surgery.

Topical corticosteroids vary in their IOP elevation effect (from the strongest effect to the least: dexamethasone 0.1%, prednisolone 1%, fluorometholone 0.1%, medrysone 1%)<sup>7</sup> to reduce steroid response, minimize the strength, frequency, and duration of corticosteroids. If possible, an individual's IOP steroid response should be elucidated *before* using depot corticosteroids.

Monitoring IOP is essential in all patients receiving corticosteroids. Once use of topical corticosteroids has ceased, IOP almost always returns to baseline within 4 weeks.<sup>10</sup> Steroid response is possible even after glaucoma surgery (microinvasive glaucoma surgery [MIGS], deep sclerectomy, or trabeculectomy). In uveitis treatment, steroids show variable effects on IOP, depending on their influence at that time on rates of aqueous inflow, outflow, viscosity, and the BAB (Table 10.16.1).

Permanent direct trabecular meshwork tissue damage can result from the following:

- Anterior and/or limbal scleritis.
- Destructive or degenerative connective tissue diseases.
- Chemical injuries, including those caused by caustic soda, ammonia, formalin, nitrogen mustards, and chloroform.
- Post-trabecular outflow damage from scleritis with vasculitis—lymphocytes surround intrascleral outflow channels, with an anterior uveal perivasculitis.
- Hypersecretion may occur in uveitis but is difficult to quantify—BAB breakdown renders fluorophotometry inaccurate; may contribute to glaucomatocyclitic crises, but flow probably normal.<sup>11</sup>

## Pre-Existing Open-Angle Glaucoma

Elevated IOP in an eye with uveitis does not mean that inflammation is the cause. Other primary or secondary forms of open-angle glaucoma, such as post-traumatic (particularly if unilateral) or pseudo-exfoliative (may be unilateral or bilateral) glaucoma, must be ruled out.

An acute onset and unilaterality suggest uveitis as the cause, whereas an afferent pupil defect with asymmetrical disc cupping and perimetric loss in a patient with a short symptomatic (uveitic) history suggests a chronic underlying glaucomatous process.

**TABLE 10.16.1** Effects of Corticosteroid Therapy on Intraocular Pressure in Ocular Inflammation

Action	Result	Effect on IOP
Decrease trabecular meshwork inflammation	Increased trabecular meshwork outflow	Decrease
Increase blood–aqueous barrier	Decreased aqueous viscosity Increased trabecular meshwork outflow	Decrease
Decrease ciliary body inflammation	Aqueous inflow returned to normal	Increase
Alter trabecular meshwork endothelial cells in corticosteroid responders	Decreased trabecular meshwork outflow	Increase

IOP, Intraocular pressure.

## Secondary Angle-Closure Glaucoma

Peripheral anterior synechiae (PAS) commonly complicate uveitis and, if allowed to progress, may seal the angle partly or completely, thus raising IOP.

PAS may follow organization of inflammatory debris or protracted iridotrabecular contact from an acute secondary angle-closure attack, a flat or shallow anterior chamber after incisional surgery, or an exudative retinal detachment with anterior displacement of the lens–iris diaphragm. Ciliary body rotation anteriorly from uveitis-induced swelling or suprachoroidal exudation can produce the same result. Swelling of the peripheral iris and exudation of proteins and other inflammatory products, such as fibrin into the chamber angle, increase PAS formation.

Neovascularization of the anterior chamber angle with subsequent fibrovascular closure may follow chronic uveitis.

Posterior synechiae form with fibrin, with later fibrovascular organization. Involvement of the entire pupil margin results in a secluded pupil; iris bombé produces a shallow or closed peripheral anterior chamber with normal central depth. PAS follow if this acute secondary angle-closure is not treated promptly with one or more adequate peripheral iridectomies.

With widespread adhesion of iris to anterior lens surface, bombé may not occur evenly or at all. Lens–iris diaphragm forward movement may be the only sign of secondary pupillary block and can be confused with an underlying tendency to primary angle closure. The anterior chamber configuration should be compared with that of the fellow eye to differentiate these mechanisms. Laser iridectomy placement can be crucial. Drainage surgery may be indicated.

In the presence of uveitis, iris bombé, and a closed angle, low or normal IOP signals possible profound aqueous hyposecretion. Successful drainage surgery may precipitate the eye into phthisis bulbi, an increased risk anyway with uveitis.

## Pre-Existing Disposition to Primary Angle Closure

With pre-existing shallow anterior chamber and relative pupillary block, an acute angle-closure crisis may be precipitated by anterior segment edema and inflammation, increased aqueous viscosity, swelling and forward rotation of the ciliary body, and anterior shift of the lens–iris diaphragm. All or some of these factors may accompany uveitis. The depth of the contralateral anterior chamber will confirm this diagnosis.

## Combined-Mechanism Glaucoma

Usually, raised IOP associated with uveitis results from more than one of these mechanisms. The mix may change as the disease and its treatment proceed. Recognizing the responsible mechanism(s) at any time point enables effective antiglaucoma therapy.

## PRINCIPLES OF MANAGEMENT

Both the underlying inflammation and the glaucoma require assessment, diagnosis, and directed treatment. Management demands flexibility as the disease(s), the effects on the eye(s), and the treatment itself may change significantly over time. An open mind and careful examination and re-examination are vital for therapeutic success.

## UVEITIS

### Diagnosis

A careful history with a review of systems and a complete ocular examination followed by targeted investigations should allow accurate diagnosis of the majority of ocular inflammations. Refer to the sections on uveitis, keratitis, and scleritis. Box 10.16.2 lists the conditions that commonly raise IOP.

### Management

Detected ocular and any associated systemic diseases are treated on their merits. Active inflammation should be controlled adequately, and its damaging effects on aqueous circulation and drainage prevented, and elevated IOP controlled (Table 10.16.2). Management in collaboration with uveitis specialists and general physicians is highly recommended, particularly when systemic medication is required.

**BOX 10.16.2 Inflammatory Conditions Commonly Associated With Raised Intraocular Pressure**

- Anterior uveitis
  - HLA-B27–related acute anterior uveitis = 20% (0%)
  - Glaucomatocyclitic crisis (Posner–Schlossman syndrome) = 100% (0%)
  - Phacolytic glaucoma
  - Herpes virus–associated uveitis = 30% (29%)
  - Fuchs’ heterochromic iridocyclitis
  - Juvenile idiopathic arthritis–associated uveitis
  - Chronic anterior uveitis
- Intermediate uveitis (pars planitis)
- Posterior uveitis
  - Peripheral anterior synechiae
  - Sarcoidosis = 34% (39%)
  - Behçet’s disease = 21% (50%)
  - Toxoplasmosis = 12% (36%)
  - Vogt–Koyanagi–Harada syndrome = 16% (34%)
  - Sympathetic ophthalmia
  - Acute retinal necrosis
  - Masquerade syndromes
  - Retinal detachment, uveitis, and glaucoma (Schwartz’s syndrome)

Percentages are cases with raised intraocular pressure (% with abnormal perimetry).

HLA, Human leukocyte antigen.

**TABLE 10.16.2 Treatment Guidelines for Inflammatory Glaucoma**

1. Treat Underlying Systemic Disease (if present)		
Specific	e.g., Anti-infectives	Specific treatment for toxoplasmosis, toxocariasis, Lyme disease, syphilis, TB
Nonspecific	Anti-inflammatory	Corticosteroids, NSAIDs
	Immunosuppression	Corticosteroid-sparing agents: methotrexate, cyclosporine, mycophenolate, mofetil, azathioprine, cyclophosphamide
	Biologicals	Anti-TNF agents, e.g., infliximab, adalimumab interferon
2. Treat Ocular Inflammation		
Specific	E.g., Intravitreal antibiotics for bacterial endophthalmitis	
Nonspecific	Anti-inflammatory	Topical, depot, intravitreal or systemic corticosteroids, NSAIDs
	Pupillary dilation	Cycloplegic, sympathomimetic agents
3. Treat Elevated IOP		
Medical	Reduce aqueous production Increase uveoscleral outflow	Beta-blockers, alpha-2-adrenergic agonists, carbonic anhydrase inhibitors Prostaglandin analogs
Surgical	Peripheral iridectomy	For pupillary block, if present with recurrence after laser iridectomy(ies)
	Augmented trabeculectomy	If medications are insufficient
	Glaucoma drainage devices	If augmented trabeculectomy fails
	Cyclodestruction: transscleral or endoscopic laser, cryotherapy	For eyes with little visual potential

IOP, Intraocular pressure; NSAIDs, nonsteroidal anti-inflammatory drugs; TB, tuberculosis.

Corticosteroids nonselectively inhibit most inflammatory reactions, irrespective of cause; they do not treat the cause. Corticosteroids aid IOP control by treating trabeculitis and by restoring the BAB; the balance can shift to higher IOP with corticosteroid responsiveness and recovery of aqueous production with resolution of iridocyclitis. Corticosteroids remain the first-line treatment for inflammation.

Nonsteroidal anti-inflammatory drugs (NSAIDs) and immunosuppressive drugs (methotrexate, cyclosporine, mycophenolate mofetil, azathioprine, cyclophosphamide) are indicated alone or in combination with one another or with corticosteroids, if corticosteroids alone have failed to control inflammation or are contraindicated. These steroid-sparing agents are particularly useful in chronic uveitides in corticosteroid-responsive

patients. Biological agents, particularly anti-tumor necrosis factor blockers, are increasingly being incorporated into uveitis treatment.

In addition to anti-inflammatory measures, antibiotics and antifungal agents are necessary when inflammation is secondary to a specific infection (e.g., toxoplasmosis).

### Mydriasis and Cycloplegia

Pupillary dilation with cycloplegics (atropine, homatropine) and sympathomimetics (phenylephrine) prevents formation of posterior synechiae or breaks them, thereby avoiding a secluded pupil. These drugs help control IOP by increasing uveoscleral outflow and by stabilizing the BAB. By decreasing ciliary muscle spasm, they may relieve discomfort.

### GLAUCOMA

In most eyes with acute inflammation, the optic disc is healthy and may withstand elevated IOP levels even into the 30s for weeks or months. Controlling inflammation and protecting the eye from damage to aqueous circulation and drainage mechanisms will normalize IOP. IOP reduction per se may not be required unless levels are thought to be unsafe, disc decompensation appears, other risk factors predispose additionally to retinal vein occlusion, corneal endothelial disease contributes to edema, or recurrent or chronic inflammation provokes long-standing ocular hypertension. Because any type of glaucoma that develops can cause rapid progression of inflammation, this requires careful monitoring.

### Medical Management

Reduction of aqueous production is the cornerstone of medical management of raised IOP with inflammation by using beta-blockers (timolol, betaxolol, carteolol, levobunolol), alpha-2-adrenergic agonists (apraclonidine, brimonidine), and topical or systemic carbonic anhydrase inhibitors (dorzolamide, brinzolamide, acetazolamide, dichlorphenamide, methazolamide). Latanoprost, travoprost, and bimatoprost in uveitis are now accepted and have been used effectively in many uveitic eyes without sequelae.<sup>4</sup> Exacerbation of uveitis and cystoid macular edema were concerns; nonetheless, these agents should be used cautiously. NSAIDs reduce the ocular hypotensive effect of brimonidine and, possibly, latanoprost.<sup>12,13</sup> Prostaglandins should be avoided in herpetic keratouveitis.

Because they enhance posterior synechiae formation by aggravating BAB breakdown, by producing miosis, and by contributing to anterior chamber shallowing, miotics (pilocarpine, carbachol) should be avoided.<sup>14</sup> They may exaggerate discomfort with ciliary muscle spasm and may raise IOP paradoxically by failing to improve trabecular outflow while blocking uveoscleral outflow.

### Surgical Management

Laser peripheral iridectomy (LPI) is indicated if posterior synechiae precipitate a secluded pupil with iris bombé and if medical mydriatic measures fail to break them. To eliminate pupillary block, the iridectomy(ies) must be adequate in size and position. LPI can raise IOP and exaggerate anterior uveitis; it can be difficult technically because of iris congestion. Gentle argon laser flattening (settings: 200–500 mW, 0.2–0.5 s, 200–500 µm spot) or “chipping” pretreatment (settings: 800–1000 mW, 0.02 s, 50 µm spot) may facilitate neodymium:yttrium–aluminum–garnet (Nd:YAG) laser penetration of the iris. Laser openings may close with active inflammation and should be monitored carefully; surgical iridectomy may have to be considered in this situation. In eyes with severe uveitis, particularly in children, a larger surgical iridectomy may be preferable to Nd:YAG iridectomy because it minimizes inflammation and is less likely to cause closure.

Argon laser trabeculoplasty (LT) can exacerbate anterior uveitis and promote PAS formation; it has a poor chance of reducing IOP significantly.<sup>15</sup> It is contraindicated in inflammatory glaucoma. Selective laser trabeculoplasty has not yet been evaluated adequately in these eyes. In corticosteroid-induced glaucoma, it may be effective.

Filtration surgery becomes necessary when medical and laser management, along with treatment of both inflammation and its cause, cannot reduce the IOP below levels that are causing or likely to cause optic disc decompensation and functional damage. Because of increased postoperative inflammation and a greater risk of profound hypotony leading to bleb failure, filtering surgery is less likely to succeed in inflamed eyes than in those with primary open-angle glaucoma.<sup>16</sup> One of the keys to success in all drainage surgery is to control inflammation maximally both before and

after surgery with, for example, intensive topical, local, or even systemic corticosteroids.

Adjunctive antifibrotic agents (intraoperative mitomycin C,<sup>17</sup> postoperative 5-fluorouracil<sup>18</sup>) have improved trabeculectomy success rates appreciably—both in the short term and in the long term. Complication rates increase, however, with these agents, the most serious ones being hypotonous maculopathy and late endophthalmitis from leaks through thin-walled blebs.

Glaucoma drainage devices (GDDs), both valved (Ahmed) and non-valved (Molteno and Baerveldt) have had more success than unaugmented trabeculectomies. GDDs do not achieve the low levels of IOP (7–11 mm Hg) that augmented trabeculectomies often can. In eyes with extensive optic disc damage, a GDD-attained IOP of 14–18 mm Hg may not be sufficiently protective. In eyes with visual potential, a GDD is indicated where augmented trabeculectomies have failed.<sup>19</sup> GDD tubes must be patched with donor sclera or equivalent to minimize the risk of later erosion, especially in uveitic glaucoma. In chronic uveitic glaucoma where aqueous production is borderline and hypotony risk is high, a smaller GDD (single plate Molteno or 250 mm<sup>2</sup> Baerveldt or Ahmed) is preferable to larger devices. Reducing aqueous production by damaging ciliary epithelium (cyclodestruction) by Diode, Nd:YAG or ultrasound energy has been used to lower IOP. Because they may aggravate ocular inflammation and lower IOP unpredictably (with significant risk of secondary phthisis bulbi or failure to control IOP), as well as the albeit small risk of sympathetic ophthalmia, cyclodestruction is recommended where all else has failed and where there is little visual potential.<sup>20</sup> Lower laser power settings are prudent, and lasers delivering lower doses, such as the micropulse laser and endoscopic laser, may be preferable. Drainage surgery after ciliary body destruction in an inflamed eye is a likely setting for hypotony and phthisis bulbi. Deep sclerectomy and newer surgeries, such as MIGS, need further evaluation in uveitic glaucoma.

## SPECIFIC ENTITIES

Table 10.16.2 highlights conditions associated with ocular inflammation and glaucoma etiologically. (Refer to other chapters for more detail.)

### Glaucomatocyclitic Crisis (Posner–Schlossman Syndrome)

In 1948, Posner and Schlossman described nine patients with this entity.<sup>21</sup> Clinical features include episodic, unilateral markedly elevated IOP (usually 40–60 mm Hg), associated with a mild anterior uveitis. Recurrences are always in the same eye. Posterior synechiae and PAS are absent, and the drainage angle remains open. Each attack lasts from a few hours to a month, but usually for 1–3 weeks. Antiglaucoma treatment does not abbreviate the attack, and iridectomy or filtering surgery does not prevent recurrences. Glaucomatous optic neuropathy may occur. Between attacks, there are generally no signs or symptoms of inflammation or glaucoma, and the contralateral eye remains normal. Of unknown etiology, although infection (with cytomegalovirus [CMV], herpesvirus, or *Helicobacter pylori*) has been implicated, this condition has a complex relationship with primary open-angle glaucoma.<sup>22–27</sup>

Management comprises the following:

- Hypotensive measures—apraclonidine or brimonidine seems particularly effective during attacks, with supplementation as required with other aqueous suppressants. The role for prostaglandin derivatives has yet to be established. Rarely, hyperosmotic agents may be needed.
- Anti-inflammatory measures—although there is no evidence that corticosteroids and/or topical NSAIDs shorten the attack or prevent recurrences, many clinicians consider them “useful.” Cycloplegics are not needed.

Intervals between attacks vary from a few days to several years. Some are seasonal. Attacks are rare in older adults, suggesting a self-resolving course. Thus prevention of irreversible disc and field damage is all the more important.

An anterior chamber paracentesis may reveal an infectious etiology for Posner–Schlossman syndrome, which, in turn, may guide specific therapy

directed against that agent, rather than treatment of elevated IOP. Should aqueous polymerase chain reaction (PCR) reveal CMV, for example, treatment with ganciclovir may be curative of the IOP elevation. Topical ganciclovir ointment, in addition to oral valganciclovir, can be of benefit; however, systemic treatment is necessary in the case of CMV infection.<sup>25</sup> Valganciclovir is not benign, and the patient must be monitored closely to detect any treatment toxicity.

### Fuchs’ Uveitis Syndrome (Fuchs’ Heterochromic Iridocyclitis)

More expansive than the one described by Fuchs in 1906,<sup>28</sup> this condition encompasses a chronic, usually unilateral (90%), low-grade panuveitis with rapid cataract formation (commencing as posterior subcapsular) and a high risk of secondary open-angle glaucoma. This entity is differentiated from other inflammatory glaucomas by the lack of posterior synechiae and the rarely more than “moderate” anterior chamber cells and flare; it is asymptomatic. Vitreous cells are common. Characteristically, keratic precipitates are small, round or stellate, and discrete; they cover the entire corneal endothelial surface and fine filaments are often seen between them. Their presence and extent greatly exceeds the inflammation. Rubella has been implicated as the inciting event,<sup>29</sup> as has CMV infection.<sup>25–27</sup> Anterior chamber paracentesis with aqueous PCR is recommended in Fuchs’ heterochromic iridocyclitis, as for Posner–Schlossman syndrome. Should an infectious etiology be present, treatment is described as above for Posner–Schlossman syndrome, specific for the infectious agent. This may eliminate the need for ocular antihypertensive treatment, with IOP normalization. Fuchs’ uveitis syndrome (FUS) and Posner–Schlossman syndrome may be thought of as part of a spectrum of uveitic glaucomas and may share the same infectious etiology.

Unless an infectious etiology for FUS is found, therapy of the uveitis is unnecessary, although a short intensive trial of corticosteroids may help to confirm the diagnosis (by lack of response). When the eye is symptomatic, short bursts of topical corticosteroids may restore comfort, but corticosteroids do not normalize the BAB or achieve total quiescence. The glaucoma is more difficult to control.<sup>30</sup> Initially, a raised IOP may respond to anti-inflammatory treatment, but in two thirds of patients, a chronic IOP rise often resists medications. Argon LTP is “underwhelming” in its effect and is contraindicated by angle changes. Selective laser trabeculoplasty has not been evaluated. Should an augmented trabeculectomy fail, GDDs may prove helpful.

Patients require ongoing monitoring, especially for glaucoma damage and for progressive iris atrophy, which hint at a poor prognosis. Recognition is important; it renders anti-inflammatory therapy unnecessary.

# Glaucoma Associated With Ocular Trauma

10.17

*Tony K.Y. Lin, David P. Tingey, Bradford J. Shingleton*

**Definition:** Glaucomatous damage to the optic nerve related to elevated intraocular pressure associated with acute or prior ocular trauma.

## Key Features

- Previous blunt or penetrating ocular trauma—glaucoma is more likely to follow blunt trauma.
- Angle recession—the greater the number of clock hours recessed, the more likely glaucoma is to occur, even months, years, or decades after the injury.
- Hyphema—often accompanies angle recession, and may be an acute cause of elevated intraocular pressure, especially in the presence of hemoglobinopathies (e.g., sickle cell disease or trait).

## Associated Features

- Trabecular tears/trabeculitis.
- Angle recession.
- Iridodialysis.
- Pupillary sphincter tears.
- Cyclodialysis.
- Zonular dehiscence.
- Lens damage, subluxation, or dislocation.
- Vitreous hemorrhage—may lead to ghost cell glaucoma.
- Retinal dialysis/retinal tear.

## INTRODUCTION

Glaucoma may occur in traumatized eyes in the period immediately following injury or years or decades later. There exist a plethora of potential causes of glaucoma following ocular trauma. It is important for the evaluating ophthalmologist to be familiar with the various types of glaucoma in this setting as well as their pathogenesis. Recent cohort studies have examined the relationship between glaucoma after ocular injury and several baseline structural and functional ocular characteristics. The risk of developing glaucoma in 3627 patients in the United States Eye Injury Registry with penetrating ocular injury was 2.67%. The development of glaucoma in these patients was independently associated with advancing age, lens injury, poor baseline acuity, and inflammation.<sup>1</sup> In a similar study, 6021 patients who experienced ocular contusion injury were found to have a risk of developing glaucoma of 3.39% at 6 months after their injury. The development of glaucoma was independently associated with the following factors:

- Advancing age.
- Visual acuity worse than 20/200.
- Iris injury.
- Lens injury.
- Angle recession.<sup>2</sup>

Ultrasound biomicroscopy (UBM) was used in conjunction with clinical features to determine early predictors of traumatic glaucoma after closed globe injury prospectively in 40 consecutive eyes.<sup>3</sup> This study found that the best clinical indicators for the development of chronic glaucoma

included degree of trabecular pigmentation, angle recession more than 180°, hyphema, lens displacement, and higher baseline intraocular pressure (IOP). UBM findings that were significant predictors of chronic glaucoma included a wider angle and the absence of cyclodialysis.<sup>3</sup>

In the initial period after an ocular injury, the IOP may be normal, high, or low. There are several mechanisms that explain a low pressure. These mechanisms include aqueous hyposecretion based on ciliary contusion and inflammation, increased egress of aqueous through a cyclodialysis cleft, or loss of integrity of the wall of the globe. The presence of ocular hypotension or normal IOP does not preclude the development of glaucoma at a later date. Whether glaucoma is present initially or at a later date, it is generally a reflection of reduced facility of outflow of aqueous humor.

One may categorize the existence of traumatic glaucoma relative to the time of onset of the glaucoma (immediate or delayed) and the type of trauma that caused the injury. The type of trauma may be divided into blunt force trauma or penetrating trauma. A broader classification would include chemicals, electromagnetic radiation, and surgery as additional causes of trauma that might induce glaucoma. Glaucoma may also occur as a result of the therapeutic modalities employed to treat the initial injury.

## IMMEDIATE OR EARLY-ONSET GLAUCOMA AFTER OCULAR TRAUMA

### Contusion

IOP elevation in the setting of blunt trauma with a notable absence of clinical evidence of tissue damage may be noted on occasion. Gonioscopy is entirely normal with no evidence of angle recession, and there is no evidence of blood or abnormal pigment in the angle. Flare and cells may be evident at the slit lamp. The presumed mechanism of this type of glaucoma is reduced outflow facility as a result of trabecular inflammation. The course of this glaucoma is usually brief and self-limiting, although a trial of topical anti-inflammatory drops in addition to any IOP-lowering agents may hasten improvement and shorten the clinical course.

### Trabecular Disruption

Evidence of trauma-related changes to the trabecular meshwork has been documented in a study utilizing gonioscopy performed within the first 48 hours following injury. Documented abnormalities ranged from sharply demarcated hemorrhage into Schlemm's canal and possibly the outer trabecular sheets to full-thickness rupture of the trabecular meshwork for part of its circumference. A trabecular flap may be created with a point of rupture at or just below the insertion of the trabecular sheets at Schwalbe's line. This flap is typically hinged in the region of the scleral spur. Such lesions at the trabecular meshwork may or may not be associated with elevated IOP at the time of injury. Trabecular lesions may scar with time and become increasingly difficult to recognize over time. Although angle recession is associated with the late development of glaucoma, the occurrence of late glaucoma may correlate better with the amount of trabecular disruption observed acutely.<sup>4</sup>

### Hyphema

The presence of hyphema (Fig. 10.17.1) after ocular trauma is an indicator of significant intraocular injury. Cho et al. compared the clinical

**Fig. 10.17.1** Blood layering (arrow) in the anterior chamber (hyphema). (From Schuman JS, Christopoulos V, Dhaliwal D, et al. *Rapid diagnosis in ophthalmology series: lens and glaucoma*. St Louis, MO: Elsevier; 2007.)

characteristics of 18 patients with very poor visual outcome after nonperforating hyphema to 166 patients with better visual outcome after nonperforating hyphema. The presence of posterior segment injuries, anterior segment injuries, poor initial visual acuity, glaucoma, vitreous hemorrhage, and eyelid laceration were all associated with long-term poor visual outcome.<sup>5</sup> Hyphema may produce glaucoma via several mechanisms, including contusion/inflammation of the trabecular meshwork, physical disruption of the meshwork, and plugging of the meshwork by red blood cells (RBCs). In addition, a large clot in the anterior chamber may even produce pupillary block by entirely occluding the pupillary aperture.

Elevation of IOP in association with hyphema may threaten vision as a result of optic nerve damage, compromised blood flow to the posterior segment, or corneal blood staining. IOP elevation occurs in up to 27% of patients acutely; however, this elevation is often mild and self-limiting.<sup>4</sup>

The duration and level of IOP required to damage the optic nerve for a given individual is difficult to determine. Read and Goldberg<sup>6</sup> studied 137 patients with hyphema prospectively and determined that optic atrophy tended to occur with IOPs at or greater than 35 mm Hg with durations varying from 5–14 days. Optic atrophy as a direct result of the trauma itself may be a confounding factor in such studies.

Corneal blood staining occurs more readily in the presence of IOP that is greater than 25 mm Hg and has persisted for at least 6 days in the setting of blood clot apposition to the corneal endothelium.<sup>6</sup> If the corneal endothelial cells are already compromised as a result of the trauma itself or pre-existing disease, the risk of staining with only marginal pressure elevation is even greater.

Sickle cell disease represents a unique challenge in the hyphema patient. Even small amounts of blood in the anterior chamber of such patients may result in severe IOP elevation.<sup>7</sup> Sickled erythrocytes presumably obstruct the outflow apparatus. Optic atrophy has also been reported in such patients with only mild pressure elevation.<sup>7,8</sup> Compromised blood flow to the optic nerve as a result of sickling has been proposed as a mechanism for this. These complications may be seen in patients with either sickle cell disease or trait. In addition, several of the conventional IOP-lowering pharmacological agents may be harmful to patients with sickle cell hemoglobinopathy. Carbonic anhydrase inhibitors may produce systemic acidosis, which enhances sickling. Methazolamide may be a safer choice than acetazolamide in this setting because it causes less systemic acidosis. Both carbonic anhydrase inhibitors and osmotic agents increase hemoconcentration and viscosity because of their diuretic effect. This, in turn, may compromise blood flow in a system already at risk from sickled erythrocytes. Acetazolamide can increase ascorbate in the aqueous humor, and this may worsen the sickling process as well. Epinephrine agents and less specific alpha-agonists, such as apraclonidine, may cause vasoconstriction, which may also compromise ocular blood flow in patients with sickle cell disease. The presence of hyphema in the patient calls for the judicious use of pharmacological agents to control even mild pressure elevation and a lower threshold on the part of the clinician for performing a washout of erythrocytes from the anterior chamber. There are reports of successful use of intracameral tissue plasminogen activator in a patient with sickle cell disease as well as traumatic hyphema and acute glaucoma.<sup>9</sup>

Rebleeding into the anterior chamber can be a devastating complication, which typically occurs between days 2 and 6 after the initial injury. The reported incidence of rebleeding is somewhere between 6% and 33%, as reported by several studies.<sup>6,8,10,11</sup> Markedly elevated IOP and its attendant complications are a particular concern with rebleeding.

Various treatments, such as those using aminocaproic acid, tranexamic acid, corticosteroids, and cycloplegics, are employed to decrease the rate of rebleeding in patients with hyphema. Aminocaproic acid and tranexamic acid are antifibrinolytic agents that decrease the rate of rebleeding; however, studies on these two agents have not shown any significant benefit to best vision or final visual acuity after traumatic hyphema.<sup>8,11–14</sup> Aminocaproic acid use is associated with significant side effects, including nausea, vomiting, gastrointestinal upset, increased systemic thrombosis risks, and systemic hypotension.<sup>11</sup> The side-effect profile of tranexamic acid is similar but with fewer gastrointestinal side effects.<sup>11,12</sup> These findings, as well as the relatively low incidence of rebleeding overall, may account for the limited use of antifibrinolytic agents by clinicians.

Corticosteroids have been used to reduce the incidence of rebleeding as well.<sup>15,16</sup> The rationale behind this is the reduction of inflammation, stabilization of blood–ocular barrier, or direct inhibition of fibrinolysis, thus preventing secondary rebleeding. However, studies examining either oral corticosteroids<sup>13,17</sup> or topical corticosteroids<sup>18,19</sup> failed to find significant differences in the time to resolution of primary hemorrhage or rates of rebleeding.

Cycloplegics and miotics have both been studied with inconclusive findings because of low rates of rebleeding.<sup>18,20</sup> Other lesser known treatment modalities, such as use of conjugated estrogen and aspirin, have been shown to have no benefit.<sup>21,22</sup>

Acute IOP elevation in the setting of hyphema may be treated with conventional pharmacological agents, with the exception of miotic agents and prostaglandin agents. Both these agents may exacerbate any pre-existing inflammation, and so they are not generally used as first-line agents. Cycloplegic agents and topical corticosteroids are often employed in the treatment of any associated inflammation after hyphema. The potential for either topical or systemic corticosteroids to produce IOP elevation with more chronic use must be kept in mind.

If the IOP remains elevated at a level that threatens the optic nerve or the cornea in spite of medical therapy, then surgical intervention may be necessary. Many surgical procedures including anterior chamber washout,<sup>23</sup> mechanical clot expression,<sup>24</sup> delivery of the clot with a cryoprobe,<sup>25</sup> automated hyphemectomy,<sup>26</sup> and ultrasonic emulsification and aspiration of the clot,<sup>27</sup> have been reported in the literature. Trabecular gonioaspiration has been reported as a successful way of managing pressure elevation resulting from blood obstructing the trabecular meshwork in patients with the sickle cell trait.<sup>28</sup> Adjunctive procedures may include peripheral iridectomy to relieve clot-induced pupillary block.<sup>29</sup> Trabeculectomy has been used to achieve pressure normalization.<sup>30,31</sup> Cyclodiathermy to control recurrent bleeding has also been described.<sup>32</sup>

Paracentesis and anterior chamber washout is the simplest and safest procedure for blood cell evacuation. This can be performed by simple irrigation or by manual coaxial irrigation and aspiration. Removal of the entire clot may not be necessary. This technique also spares the conjunctiva for future filtration surgery if it becomes required.

## Massive Choroidal Hemorrhage

This is a rare cause of acute IOP elevation after ocular trauma. At the slit lamp, a shallow anterior chamber, both axially and peripherally, will be seen in association with a reduced red reflex or a frank retrolenticular mass. Indirect ophthalmoscopy reveals choroidal elevation. Obstruction of the trabecular meshwork from secondary angle closure is the most common reason for IOP elevation in this setting, although other mechanisms from associated other effects of the trauma, such as hyphema, inflammation, and so on, may also play a role.

Initial treatment consists of topical IOP-lowering agents as well as oral carbonic anhydrase inhibitors and a systemic hyperosmotic agent, if needed. Miotics should be avoided because they will further make the anterior chamber shallow. Cycloplegics may be effective in deepening the anterior chamber. Oral corticosteroids may be helpful in reducing inflammation and stabilizing compromised choroidal vasculature.

Certain situations, such as persistent angle closure with IOP elevation, lens–cornea apposition, and “kissing” choroidals with retinal apposition may warrant surgical drainage of the blood in the suprachoroidal space. It is advisable to wait several days, if possible, for the blood clot to become liquefied in the suprachoroidal space before intervening.

Chronic synechial closure of the angle may be a sequela of massive suprachoroidal hemorrhage. This may require intervention in the form of chronic medical therapy, laser iridoplasty, surgical goniosynecholysis, conventional filtration surgery, or cycloablation, depending on the circumstance.

Massive choroidal detachment with intraretinal dissection is a rarely seen occurrence after trauma in the setting of age-related macular degeneration. This results in a “Y-suture” apposition of posterior segment tissues pushing the lens–iris diaphragm forward and leading to angle closure.<sup>33</sup> IOP rises dramatically, and vision is often reduced to no light perception. Medical or surgical therapy rarely restores vision.

## Chemical Trauma

Alkali burns produce tissue saponification, resulting in severe damage to the ocular structures. Acid burns are often self-limiting as a result of tissue coagulation. Glaucoma is more often associated with alkali burns.

Glaucoma as a result of alkali burns may be immediate or delayed. In 1946, Hughes<sup>34</sup> documented several cases of elevated IOP with delayed onset after an alkali burn. Several papers in the 1960s documented acute pressure elevation after alkali burn.<sup>35,36</sup> The angle was gonioscopically open in these cases.

The nature of the acute IOP rise has been studied in rabbits by Chiang et al.<sup>37</sup> These authors demonstrated a dicrotic rise in IOP following the application of sodium hydroxide. In the rabbit model, there was an immediate rise of 40 mm Hg in IOP, followed by a gradual decline in pressure to 20 mm Hg above normal in 10 minutes. The IOP again rose gradually reaching 40 mm Hg above normal at 1 hour. The IOP was 20 mm Hg above normal at 3 hours after the alkali application.

The mechanism of IOP rise in rabbits following alkali application was elucidated by Paterson and Pfister.<sup>38</sup> They implicated tissue shrinkage involving the outer coats of the eye in the initial pressure spike. Lid contraction and extraocular muscle spasm were not thought to play an important role in pathogenesis. Prostaglandin release as part of the inflammatory cascade was thought to be the greatest contributor to the second hypertensive phase. The authors also postulated that blockage of the trabecular meshwork with inflammatory debris might also play a later role in the rise of IOP.

The potential for acute IOP elevation in the setting of alkali burn as documented in the animal model points to the importance of attempting to document IOP as early as possible after injury. In addition to the conventional therapies directed at the anterior segment consequences of an alkali burn, treatment of any IOP elevation is important. Arguably, treatment with IOP-lowering agents on a prophylactic basis is a reasonable consideration, particularly in severe burns, given the propensity for these burns to produce rapid and severe IOP elevation.

When the decision to treat with IOP-lowering agents is made, topical beta-blockers, alpha-agonists, and carbonic anhydrase inhibitors are all appropriate, as well as systemic treatment with carbonic anhydrase inhibitors and hyperosmotic agents, as needed. Miotics and topical prostaglandin analogues are generally avoided because of the inflammatory nature of this condition. Anti-inflammatory medications and adequate cycloplegia are also important. Anterior chamber paracentesis with aspiration of aqueous humor may be required if the IOP is extremely high during the initial hypertensive phase. This reduces the IOP and removes inflammatory mediators, debris, and alkali directly from the anterior chamber.

After the initial alkali burn, glaucoma may appear or reappear. Ongoing inflammation with secondary peripheral anterior synechiae (PAS) and angle closure is the most common mechanism. In their study looking at the incidence of glaucoma in eyes with severe chemical burn, before and after keratoprosthesis, Cade et al. found that 21 of 28 eyes in this group had preoperative evidence of glaucoma, nine of these eyes developed glaucoma progression after keratoprosthesis implantation, and two more eyes developed glaucoma postoperatively.<sup>39</sup> The treatment of this late-onset glaucoma includes conventional medical and surgical therapies.

## LATE-ONSET GLAUCOMA AFTER OCULAR TRAUMA

### Angle Recession

The first pathological description of angle recession resulting from blunt trauma was described by Collins<sup>40</sup> in 1892. In 1949, D’Ombrain<sup>41</sup> described chronic posttraumatic glaucoma, which he attributed to a proliferative

**Fig. 10.17.2** Tear between the longitudinal and circular muscles of the ciliary body presenting as a widening (arrow) of the ciliary band (angle recession). (From Schuman JS, Christopoulos V, Dhaliwal D, et al. *Rapid diagnosis in ophthalmology series: lens and glaucoma*. St Louis, MO: Elsevier; 2007.)

lesion scarring the trabecular meshwork. No observation of pathological deepening of the anterior chamber angle was made. The pathological entity of angle recession and the clinical phenomenon of unilateral chronic glaucoma were linked by Wolff and Zimmerman in 1962.<sup>42</sup>

Anatomical recession of the anterior chamber angle (Fig. 10.17.2) is common after blunt trauma. The incidence of angle recession after traumatic hyphema ranges from 71%–100%, as indicated by several reports.<sup>43–46</sup> Glaucoma is relatively uncommon after angle recession, being found in 7%–9% of eyes.<sup>43,45,47</sup> Attempts have been made to correlate the degree of angle recession with the likelihood of developing glaucoma. Alper<sup>48</sup> believed that the risk of glaucoma developing was highest if more than 240° of the angle appeared recessed. In a population-based survey, Salmon et al. performed gonioscopy on 987 inhabitants of a small South African village. These authors found a cumulative lifetime prevalence of angle recession in the community of 14.6%. The prevalence of glaucoma in individuals with angle recession was 5.5% (8 of 146). Of 87 eyes with 360° of angle recession, only seven (8%) had glaucoma.<sup>49</sup>

The elevation of IOP from angle recession demonstrates a bimodal pattern with glaucoma occurring either within the first year or after 10 years as described by Blanton.<sup>43</sup> This author found that the earlier-onset group often had less angle recession, and the IOP rise was transient in some patients. Other authors have found recession greater than 270° more common in the early-onset group.<sup>4</sup>

Angle recession is defined pathologically as a separation between the longitudinal and circular fibers of the ciliary body muscle.<sup>42</sup> The longitudinal muscles remain attached to the scleral spur, and there is a posterior displacement of the iris root. Iridodialysis (Fig. 10.17.3) and cyclodialysis may also be observed. Lenticular changes, including subluxation, dislocation, or cataract, may occur. Late evaluation of the angle may show a broad ciliary band with a fusiform appearance attributed to atrophy of the inner circular portion of the ciliary muscle. Variable degrees of fibrosis and hyalinization of the trabecular meshwork may occur. Peripheral synechiae may also be present.

Elevated IOP immediately after injury may result from extensive angle recession, although it may also be due to other causes, as cited earlier in this chapter. The clinical presentation of glaucoma secondary to angle recession is variable and depends somewhat on the time of presentation relative to the initial injury. Often angle-recession glaucoma presents years after the initial event as a chronic unilateral glaucoma. In a pathological review of 100 eyes enucleated for unilateral glaucoma, Miles and Boniuk<sup>50</sup> found angle deformity as the principal cause for the glaucoma in 11 eyes. None of these deformities had been recognized clinically. Eight of these 11 patients gave a history of previous trauma to the eye, ranging from 6 months to 24 years before the onset of glaucoma.

Unilateral glaucoma is typically secondary, and a history of previous trauma should always be sought. Examination will often reveal clues,

**Fig. 10.17.3** Tear in the root of the iris (iridodialysis). (From Schuman JS, Christopoulos V, Dhaliwal D, et al. *Rapid diagnosis in ophthalmology series: lens and glaucoma*. St Louis, MO: Elsevier; 2007.)

including a deeper anterior chamber on the affected side, tears of the iris sphincter or root, thinning of the iris stroma, or abnormal clumps of pigmentation on the iris. As a result of pigmentary changes, the iris color may differ between the two eyes. Tonjum<sup>51</sup> has demonstrated a paralyzed or paretic pupillary sphincter in the same sector as the chamber angle deformity in acutely injured eyes. This pupillary change may recover over time. The lens may be abnormally mobile or frankly dislocated. There may be clues to previous injury in the posterior segment, including pigment in the vitreous, macular edema, retinal pigment epithelial hyperplasia, choroidal or retinal scars, or frank retinal detachment.

Gonioscopy is key in establishing a diagnosis of angle recession. The cardinal features of angle recession on gonioscopy include an exposed ciliary body face that appears wider than usual and an iris root that appears to be posteriorly displaced. Uveal processes are disrupted, and the scleral spur may appear abnormally pale or white. Comparison of the angle appearance between contralateral eyes is helpful in detecting more subtle degrees of angle recession. The technique of bilateral simultaneous Koeppel gonioscopy is most helpful in this regard. An additional gonioscopic finding is the presence of a gray-white membrane covering the angle recess which may be observed even years after the initial injury.<sup>48</sup>

Elevated IOP in angle recession is a result of significant injury to the trabecular meshwork as opposed to the more evident tear into the ciliary body. The facility of outflow, as measured by tonography, is reduced and correlates with the degree of angle recession and glaucoma.<sup>44</sup> Herschler<sup>4</sup> was able to document a high incidence of visible damage to the trabecular meshwork and Schlemm's canal in eyes undergoing gonioscopy within 48 hours of injury. These trabecular lesions decreased over time while the ciliary body tears persisted. An underlying predisposition to the development of glaucoma in some injured patients may exist. Spaeth<sup>52</sup> studied 13 patients in whom unilateral angle-recession glaucoma had developed and found that approximately 50% of these patients had evidence of frank or probable glaucoma in the fellow eye.

Angle-recession glaucoma is a secondary chronic open-angle glaucoma that is generally amenable to standard topical medications used to treat the glaucomas. Laser trabeculoplasty may be attempted provided the initial IOP is not too high.<sup>53,54</sup> Argon laser trabeculoplasty was used in one study, but it failed to lower IOP.<sup>53</sup> The use of selective laser trabeculoplasty has not been well studied and is also likely to be ineffective. Neodymium:yttrium-aluminum-garnet (Nd:YAG) laser trabeculopuncture met with some success in a small series of 11 Japanese patients with angle-recession glaucoma.<sup>55</sup> Filtration surgery is certainly an option in these patients, provided the conjunctiva is not extensively scarred by the injury itself or by related ocular surgeries, such as retinal detachment repair. Trabeculectomy may be less successful in posttraumatic angle-recession glaucoma. Mermoud et al. found the success rate of trabeculectomy for angle-recession glaucoma to be 43% in 35 consecutive patients compared with a success rate of 74% in 35 consecutive matched patients with primary open-angle glaucoma (POAG). These authors advocated the routine use of antimetabolites in such cases.<sup>56</sup> These results were also supported by a retrospective analysis of 87 drainage procedures performed over an 8-year period during which trabeculectomy with antimetabolite outperformed trabeculectomy without antimetabolite and Molteno implantation.<sup>57</sup> The

effectiveness of using mitomycin C in filtering surgery for angle-recession glaucoma was demonstrated in a retrospective review of 43 consecutive procedures. Cumulative probability of success was 85% at 1 year and 81% at 2 years.<sup>58</sup> Additionally, tube shunt surgery or cyclodestruction represent additional available therapeutic modalities, as indicated. A prospective case series examined 38 patients who received a Molteno implant with a mean follow-up of 10.9 years. IOP of 21 mm Hg or less (with or without hypotensive medication) occurred with a probability of 0.80 at 5 years and 0.72 at 10 years.<sup>59</sup>

More recently, de Kierk and Au reported successful treatment of angle-recession glaucoma with the i-Stent in two patients.<sup>60</sup>

## Peripheral Anterior Synechiae

PAS are a product of apposition of iris to the angle structures or peripheral cornea in the setting of inflammation. Ocular trauma can provide these conditions on occasion. Organization of blood and inflammatory debris in the angle can occur after hyphema. Penetrating trauma may shallow the chamber for extended periods, resulting in extensive synechial closure of the angle. Endothelialization of the angle has been observed after blunt trauma, and this can pull the angle closed. Epithelial or fibrous downgrowth after penetrating trauma will produce angle closure. Massive choroidal hemorrhage after trauma will push the angle closed and sets up an inflammatory cascade, often leaving the angle closed after the hemorrhage has resolved. The potential for synechial closure necessitates careful and repeated gonioscopy after a traumatic event.

Treatment of synechial closure can often be directed at attempting to reopen the angle, particularly if the intervention occurs early rather than late. Iridogonioplasty with the argon laser may be sufficient to pull the iris away from the angle. Failing this, surgical goniosynechialysis may be effective in reopening the angle for filtration. If the angle is permanently closed, with ensuing high IOP, therapy is directed at lowering the pressure with more conventional medical and surgical methods.

## Ghost Cell (Hemolytic) Glaucoma

Campbell et al. initially described ghost cell glaucoma by demonstrating that after vitreous hemorrhage, fresh RBCs degenerated into ghost cells in the vitreous usually within 1 or 2 weeks.<sup>61</sup> If there is hyaloid face disruption, the ghost cells gain access to the anterior chamber. Ghost cells differ from normal RBCs in that they are rigid and do not pass through the meshwork easily. These cells obstruct outflow and produce an elevation of IOP.

An early review of ghost cell glaucoma by Campbell examined the clinical characteristics of 14 patients, all of whom had a traumatic ghost cell glaucoma.<sup>62</sup> A common clinical course of severe trauma resulting in anterior chamber and vitreous hemorrhage was followed by clearing of the anterior chamber blood; however, the fresh RBCs in the vitreous gradually converted to ghost cells. These cells had a characteristic ochre color and were found both in the posterior and anterior segments. Occasionally, ghost cells would layer out in the anterior chamber creating a "pseudo-hypopyon." Ghost cell glaucoma occurred anywhere from 2 weeks to 3 months after the trauma but was most common 1 month after the injury. The IOP was usually very elevated, ranging from 30–50 mm Hg.

Histopathological examination of one eye demonstrated ghost cells in the anterior chamber with a relatively normal-looking angle. Macrophages laden with RBC debris were evident in the vitreous cavity as well as free ghost cells in the vitreous cavity. The anterior hyaloid face was disrupted, allowing passage of the ghost cells into the anterior chamber. Phase contrast microscopy demonstrated a crenated shrunken appearance of the ghost cells, with Heinz bodies demonstrating denatured hemoglobin present in the cytoplasm of some of the ghost cells.<sup>62</sup>

Standard glaucoma medical therapy is initially employed to treat ghost cell glaucoma, although Campbell found that less than half of patients are controlled by medical therapy alone.<sup>62</sup> Initial surgical intervention involves washing the ghost cells out of the anterior chamber. If this is unsuccessful, a pars plana vitrectomy may be necessary to ensure complete removal of the cellular load from the eye.

## Lens-Induced Glaucoma

These comprise a group of glaucomas that share the lens as a common pathway in their pathogenesis. Lens-induced glaucomas can be further subdivided by their angle configuration with secondary angle-closure

glaucoma caused by lens dislocation/ectopia lentis and phacomorphic glaucoma and secondary open-angle glaucoma caused by phacolytic, phacoantigenic, and lens particle glaucoma.

### Lens Dislocation

Trauma of a sufficient magnitude may disrupt the zonules resulting in subluxation or dislocation of the lens. Pupillary block with angle closure may result from forward advancement of the lens. Pupillary block may also be the result of vitreous blocking the papillary aperture if the lens has dislocated posteriorly.

The onset of angle-closure glaucoma with pupillary block may present acutely with a painful red eye, corneal edema, and severely elevated IOP, mimicking acute angle-closure glaucoma with primary pupillary block. The chamber will appear shallow both axially and peripherally with iris convexity. The angle will appear closed on gonioscopy. A previous history of trauma and an axially deep chamber in the fellow eye with a wide open angle on gonioscopy all point to traumatic lens subluxation. In a Chinese study of 526 cases presenting as primary acute-angle closure, 5.89% of cases were found to be secondary to lens subluxation. Previous history or signs of trauma were often neglected.<sup>63</sup> Phacodonesis may be appreciated at the slit lamp. With lens dislocation vitreous blocking, the pupil may be appreciated at the slit lamp. Evidence of lens dislocation may also be seen on ophthalmoscopy. Secondary glaucoma as a result of traumatic lens dislocation was found to occur in 88% of 106 patients in a review from China.<sup>64</sup>

Treatment of this form of glaucoma is directed at relieving the pupillary block with laser iridectomy or surgical iridectomy. Lensectomy may be required for reasons of visual rehabilitation or if the lens continues to compromise the angle or cornea after iridectomy/iridectomy because of persistent extreme anterior displacement.

### Phacomorphic Glaucoma

Phacomorphic glaucoma may be caused by a mature cataract as a result of pupillary block or direct angle compromise from mass effect. Similarly, an intumescent cataract that occurs from lens swelling can precipitate acute secondary angle-closure glaucoma acutely through the same mechanisms. Unilateral intumescent cataract with chamber depth asymmetry may result from previous ocular trauma.

Pupillary block may be relieved by laser iridectomy or surgical iridectomy. Cataract surgery is indicated to remove the underlying cause of this problem and restore vision. If chronic angle closure exists laser iridoplasty or surgical goniosynecholysis at the time of cataract surgery may be beneficial.

### Phacolytic Glaucoma

Phacolytic glaucoma is seen in the setting of a hypermature cataract. Leakage of high-molecular-weight proteins through an intact lens capsule elicit an immune response of macrophages and other inflammatory debris, which compromises outflow facility.<sup>65</sup> Treatment is the surgical removal of the hypermature cataract.

### Phacoantigenic Glaucoma

This is a rare secondary lens-induced glaucoma, previously known as *phacoanaphylaxis*. Phacoanaphylaxis is no longer used because it incorrectly implies an allergic reaction. Phacoantigenic glaucoma is a granulomatous inflammation to retained lens proteins in the eye as a result of sensitization of the immune system after cataract surgery or penetrating injury. The resulting inflammation obstructs outflow facility. Use of topical corticosteroids and IOP control comprise the initial therapy. Persistent inflammation will require the surgical removal of all residual lens protein.<sup>65,66</sup>

### Lens Particle Glaucoma

Lens particle glaucoma is a result of obstruction of the trabecular meshwork from lens fragments that have been liberated from the lens as a result of surgical or traumatic disruption of the lens capsule. These lens fragments are evident on slit-lamp examination. Treatment is directed at removal of the lens and any associated free fragments.<sup>65,66</sup>

## Delayed Closure of a Cyclodialysis Cleft

Cyclodialysis clefts represent separation between the scleral spur and the ciliary muscle. These clefts can occur as a result of trauma or surgical intervention. A cyclodialysis cleft is associated with hypotony as a result of increased egress of aqueous humor through this alternative pathway as well as decreased aqueous production. A cyclodialysis cleft can close

spontaneously or as a result of intentional intervention. When closure of the cleft occurs, the IOP may rise dramatically. Goldmann<sup>67</sup> postulated that the reduction in flow of aqueous humor across the conventional trabecular pathway during a cyclodialysis cleft results in a reduced permeability of the trabecular meshwork, which is manifest as dramatically elevated IOP after closure of the cleft.

Closure of a cyclodialysis cleft will often produce acutely elevated IOP with associated subjective symptoms, including decreased vision, ocular discomfort, and even systemic effects, such as nausea and vomiting. Corneal edema, a formed anterior chamber, and an open angle will be present. A previous history of trauma or a previously documented cleft with associated signs and symptoms of hypotony may be elicited. When closure of the cleft is a concern, reopening the cleft with miotics and phenylephrine may be effective in reopening the cleft and lowering IOP. Repeating gonioscopy after this maneuver will assist in confirming the diagnosis.

## Epithelial Downgrowth

Epithelial cells may proliferate abnormally in the anterior chamber of the eye either as a result of their introduction into the eye after penetrating trauma, or they may grow into the anterior chamber as a result of a patent fistula allowing communication between the external surface of the eye and the anterior chamber. Subsequent proliferation of these abnormally located epithelial cells can produce glaucoma as either a result of an epithelial sheet-like proliferation over the meshwork or subsequent angle closure from PAS as the epithelial sheets contract and pull the peripheral iris into the angle. This rare occurrence has a poor prognosis and is difficult to treat.

## Retained Intraocular Foreign Body

A retained foreign body may be associated with several types of glaucoma. Loss of integrity of the globe as a result of penetration may produce a shallow or flat anterior chamber. This, in association with attendant inflammation, can result in secondary angle-closure glaucoma with extensive PAS. As discussed in our previous section, penetration may introduce epithelial cells or create a fistula resulting in epithelial downgrowth and associated glaucoma. Frank disruption of the lens capsule may produce a lens particle glaucoma. Cataract formation may produce a phacomorphic glaucoma or a phacolytic glaucoma if the cataract becomes hypermature. Siderotic glaucoma may occur as a late manifestation of a retained iron-containing foreign body. This can present long after the initial trauma with associated heterochromia, mydriasis, and a rust-like discoloration of the anterior subcapsular surface of the lens and the posterior corneal surface. The existence of an occult foreign body should be suspected in this setting. A distant history of a foreign body striking the eye may be elicited. There may be clues on examination pointing to an occult foreign body, including unilateral cataract or a small lenticular capsular rupture, chronic inflammation, unilateral glaucoma, discrete areas of iris transillumination, or a corneal or scleral wound.

Dilated fundus examination may allow easy visualization of the retained foreign body. Occasionally, a foreign body is located in the anterior chamber and is found on gonioscopy. Some patients may have signs of chalcosis or siderosis, as outlined previously.

If the media are not clear enough to allow funduscopic examination, additional studies, including plain film radiography, computed tomography, and ultrasonography, are helpful in confirming the diagnosis. Reduced retinal function may also be evident with a reduction electroretinographic activity.

## Rhegmatogenous Retinal Detachment

The presence of rhegmatogenous retinal detachment often increases uveal-scleral outflow via the retinal tear resulting in a reduction in IOP relative to the fellow eye.<sup>68</sup> Ocular hypertension may occur in 5%–10% of patients with rhegmatogenous retinal detachment.<sup>69</sup> Possible reasons for this include pre-existing POAG, associated inflammation, or Schwartz's syndrome.<sup>70</sup> Schwartz's syndrome was initially described in 11 cases of rhegmatogenous retinal detachment associated with glaucoma. Five of these 11 cases were associated with previous ocular trauma.<sup>71</sup>

Matsuo et al.<sup>72</sup> elucidated the pathogenesis of this glaucoma after demonstrating photoreceptors in the aqueous humor by performing transmission electron microscopy on the aqueous humor of seven patients with this syndrome.

Unilateral glaucoma in the presence of rhegmatogenous retinal detachment is an unusual presentation and emphasizes the importance of careful fundusoscopic examination in all cases of unilateral glaucoma.

Repair of the retinal detachment promptly returns the intraocular pressure to normal, provided there are no associated ocular abnormalities, such as angle recession, likely contributing to chronic elevation of intraocular pressure.

# Glaucoma With Raised Episcleral Venous Pressure

10.18

E. Randy Craven

**Definition:** Glaucoma with elevated intraocular pressure caused by a decrease in aqueous outflow secondary to increased episcleral venous pressure.

**Key Feature**

- Unilateral elevation of intraocular pressure in an eye with prominent episcleral veins.

**Associated Features**

- Blood in Schlemm’s canal.
- Either venous obstruction or arteriovenous abnormalities.

**INTRODUCTION**

Raised episcleral venous pressure can cause open-angle glaucoma by obstructing the outflow of aqueous into the venous drainage system. Raised episcleral venous pressure can come from systemic abnormalities that can be fatal. Therefore, because of the morbidity associated with these causes, one needs to consider beyond the eye when a patient presents with an unilateral red eye and glaucoma.

**EPIDEMIOLOGY AND PATHOGENESIS**

Raising the episcleral venous pressure (ESVP) causes a similar direct rise in the intraocular pressure (IOP).<sup>1</sup> The resultant IOP is determined by the production (F) and facility of outflow (C) of aqueous humor but is one-to-one mm Hg changed by the ESVP (the Goldmann equation):

$$IOP = F/C + ESVP$$

The ESVP can be increased by the body position<sup>2</sup> and venous drainage pressure in the superior/inferior ophthalmic veins, cavernous sinus, petrosal sinuses, and internal and external jugular veins. Thus, any abnormality—including hereditary anomalies—leading to increased venous pressure in the venous drainage system downstream from the eye can lead to elevated IOP.<sup>3</sup>

An idiopathic cause to rise ESVP can lead to elevated IOP and glaucoma.<sup>4</sup> Idiopathic elevation to the ESVP does not appear to feature any extraocular venous abnormalities; color Doppler imaging has not helped to reveal any specific retro-orbital etiology to the cause of this syndrome. These patients tend to be older, without a family history of glaucoma. Unilateral presentation is common, and the right eye is more commonly involved with this syndrome. Venous and arterial abnormalities leading to elevated ESVP are summarized in Table 10.18.1.

**OCULAR MANIFESTATIONS**

Engorged episcleral veins (Fig. 10.18.1) and blood in Schlemm’s canal—best seen via gonioscopy (Fig. 10.18.2)—appear with raised episcleral venous pressure. Neovascularization of the iris can occur if there is associated anterior segment or retinal ischemia.<sup>5</sup> Hemorrhagic choroidal detachments with secondary angle closure may develop.<sup>6</sup> When the venous

TABLE 10.18.1 Venous and Arterial Abnormalities Leading to Elevated Episcleral Venous Pressure

Venous Obstruction	Arteriovenous Abnormality	Tests to Consider	Other Findings
Superior vena cava syndrome		Chest x-ray	Cyanosis
	Dural–cavernous fistula	MRI	
Thyroid ophthalmopathy	Orbital varix	MRI	Proptosis
Sturge–Weber syndrome			Skin/retina
Jugular vein obstruction			Cyanosis
Cavernous sinus thrombosis	Carotid–cavernous fistula	MRI	Pain

MRI, Magnetic resonance imaging.

**Fig. 10.18.1 Prominent Episcleral Veins.** The episcleral vessels are tortuous and appear succulent. The eye lacks the classic ciliary flush seen with iritis or infections.

pressure approaches arterial pressure in patients with arteriovenous abnormalities, the subsequent IOP elevation can be quite high.

Raised ESVP is caused by venous obstruction or arterialization of the veins (arteriovenous abnormalities; see Table 10.18.1). Examination findings may reveal proptosis, which can occur with thyroid eye disease, carotid–cavernous fistulae, or an orbital varix. An orbital varix can have positional proptosis. Carotid–cavernous fistulae can cause pulsatile proptosis. Hemangiomas associated with Sturge–Weber syndrome can involve the skin and retina (“tomato catsup” fundus). Chemosis is common with carotid–cavernous fistulae but can be seen with Sturge–Weber or thyroid ophthalmopathy.

Glaucomatous optic atrophy and visual field loss from raised ESVP can take longer than other forms of acute glaucoma—or not occur—despite very high IOPs. This is especially true in the more acute problems that present with raised ESVP, such as carotid–cavernous fistulae.

**Fig. 10.18.2 Blood in Schlemm's Canal.** Gonioscopy reveals prominent red hue over the trabecular meshwork zone of the angle.

## DIAGNOSIS

The appearance of the episcleral veins in problems with raised episcleral venous pressure is quite characteristic. The appearance of the episcleral vessels (see Fig. 10.18.1) is highly suggestive of the diagnosis. If in doubt, it is possible to measure the venous pressure to confirm or determine the level of the raised venous pressure. Five methods for determining the episcleral venous pressure have been used. The direct method for measuring the episcleral venous pressure can be done by cannulation. This is the most accurate method and reveals the episcleral venous pressure to be 5–12 mm Hg. Noninvasive methods look for a collapse in the vein (partially or totally) while a force is applied to the vein. The remaining four methods use an indirect method in which the pressure required for venous collapse can be determined by a pressure chamber (of Seidel), an air jet, a torsion balance, or an indirect method.<sup>7–8</sup> The pressure chamber or indirect (venometer) methods probably provide the most accurate readings apart from direct cannulation.

## DIFFERENTIAL DIAGNOSIS

Prominent ocular vessels can occur without increased IOP and glaucoma. The specific vessels and pattern of vessels involved differ from that seen with infections, inflammation, or allergies; usually the vessels are finer with a more diffuse hue to the pattern. Ataxia telangiectasia can cause abnormal vessels on the ocular surface but tends to be more localized to a quadrant and smaller vessels.

Scleritis and episcleritis tend to have smaller caliber vessels than with raised ESVP. Additionally, the vessels are more of a crisscross pattern with a network of deep vessels along with radial vessels and overall more diffuse involvement of the vessels. Intraocular tumors can cause prominent scleral vessels (Reese's sign). Conditions with scleral thinning, such as that seen after repeated ciliary body destructive procedures, can lead to a more prominent view of the normal veins.

## SYSTEMIC ASSOCIATIONS

Carotid-cavernous fistulae occur most often after significant trauma. Pulsating exophthalmos, blurred vision, pain, chemosis, and audible shunts

can be heard with a stethoscope. These tend to develop rather suddenly. Dural-cavernous fistulae occur commonly in middle-aged women with a more gradual onset. Superior vena cava syndrome occurs in the presence of bronchogenic carcinomas. Cavernous sinus thrombosis occurs from infections spreading from the middle ear, sinuses, or the face. Significant congestive heart failure can lead to elevated venous pressure; many findings are present, including peripheral edema and pulmonary congestion.

## TREATMENT

When elevated IOP occurs because of the elevated ESVP, it is possible to lower the IOP to the level of the ESVP but not much lower. Aggressive filtering surgery with an avascular bleb can work, but it can, therefore, be very difficult to drop the IOP satisfactorily without treating the primary cause of the raised ESVP. Treatment of fistulae can involve neuroradiological intervention or neurosurgical intervention. Dural-cavernous fistulae are low flow and can spontaneously close, whereas the carotid-cavernous fistulae tend to need intervention. Dural-cavernous fistulae are usually watched and can resolve by the patient sleeping with the head elevated or sitting for a period.

Treatment of other medical problems leading to raised ESVP should be attempted if possible. Medications that suppress the aqueous production are good first-line medication choices. Beta-blockers and carbonic anhydrase inhibitors are commonly used agents. Alpha-agonists, because of their vasoconstrictive effects on the arteries leading into the eye, are also a good first choice for medications.

Laser trabeculoplasty provides little help in most cases. Some surgeons feel nonpenetrating procedures may be a safer form of filtration surgery, and some surgeons prefer valves.<sup>9</sup> Preoperative mannitol and other pressure-lowering medications should be given. Because of the prominent vessels, a releasable suture should be considered with trabeculectomy.

## COURSE AND OUTCOME

Once the problem that caused the raised episcleral venous pressure is treated, the IOP is easier to control. If it is not possible to lower the episcleral venous pressure, such as in Sturge-Weber syndrome, the glaucoma is chronic and progressive until the IOP is controlled.

# Malignant Glaucoma

Nishat P. Alvi, Louis B. Cantor, Joshua W. Evans

10.19

**Definition:** Malignant glaucoma is a rare form of glaucoma, also known as “aqueous misdirection,” that develops primarily in patients with primary angle closure and is characterized by elevated intraocular pressure with a shallow or flat anterior chamber despite a patent iridectomy.

## Key Features

- Shallowing or flattening of both the central and peripheral anterior chamber despite patent iridectomy.
- Almost always associated with markedly elevated intraocular pressure.
- Chronic angle-closure glaucoma.
- Worsened by miotics.
- Relieved by cycloplegics and mydriatics.
- Usually occurs after intraocular surgery.
- Involves some degree of aqueous misdirection into the vitreous cavity.
- Supraciliary or suprachoroidal effusion, if present, is very small.

## Associated Features

- May occur after laser or medical therapy of glaucoma.
- Intraocular pressure may be within the normal range.

## INTRODUCTION

Aqueous misdirection glaucoma, also known as malignant glaucoma, is a rare form of glaucoma that typically follows intraocular surgery in patients with primary angle closure and primary angle-closure glaucoma (PACG). It occurs after routine cataract surgery, after the administration of miotics in eyes with or without a prior surgical history, after ciliary body swelling, or less commonly spontaneously.<sup>1</sup> It may be difficult to make an accurate diagnosis, particularly in the early stages.

## EPIDEMIOLOGY AND PATHOGENESIS

Aqueous misdirection occurs in approximately 2%–4% of patients who undergo surgery for angle-closure glaucoma, especially if some of the angle is closed preoperatively. If the angle is open or has been opened prophylactically via a laser iridectomy before the development of an angle-closure attack, aqueous misdirection seems less likely to occur after subsequent surgery.<sup>1</sup> This condition also may occur after the cessation of topical cycloplegic therapy, the initiation of topical miotic therapy, laser iridectomy, laser capsulectomy, laser cyclophotocoagulation, cataract extraction, pars plana vitrectomy, seton implantation, central retinal vein occlusion, or argon laser suture lysis, or in eyes that have hyperopia, short axial lengths, or nanophthalmos.<sup>2,3</sup>

The pathogenesis of aqueous misdirection is thought to be multifactorial. Shaffer and Hoskins suggested that there is posterior misdirection of aqueous flow by a relatively impermeable hyaloid membrane into or behind the vitreous body; the subsequent increase in vitreous volume results in a shallower anterior chamber and an increase in intraocular pressure (IOP).<sup>4</sup> Epstein and coauthors demonstrated vitreous hydration as a basic etiology for malignant glaucoma.<sup>5</sup> Quigley and colleagues suggested that choroidal thickening may predispose to angle-closure glaucoma. These changes in the choroid may result in forward rotation of the ciliary body and choroid

**Fig. 10.19.1 Aqueous Misdirection.** Note the flat anterior chamber despite a patent iridectomy.

that predisposes to malignant glaucoma.<sup>6</sup> Events that incite aqueous misdirection include a short eye, a small, crowded anterior segment, angle closure, swelling and inflammation of the ciliary processes, and anterior rotation of the ciliary body and movement of the lens–iris diaphragm forward as a result of the use of miotics. It is notable that the vast majority of reported cases of aqueous misdirection occur in the white populations rather than the Asian population even though PACG is more prevalent in Southeast Asia and China. This may potentially indicate a different etiology of angle closure in white versus Asian populations.<sup>7–9</sup>

## OCULAR MANIFESTATIONS

A red, painful eye develops immediately (or days or even months) after intraocular surgery, typically for acute angle-closure glaucoma. Its development often corresponds to the cessation of cycloplegic therapy or the institution of miotic drops. Slit-lamp examination (Fig. 10.19.1) characteristically reveals a shallow or flat anterior chamber, both centrally and peripherally (with asymmetry with respect to the fellow eye), and no iris bombé. A high index of suspicion is necessary to make the appropriate diagnosis, since initially the IOP may not be elevated much. The key is that the IOP is elevated and the anterior chamber is *axially* shallow. Furthermore, if an attempt is made to reform the anterior chamber postoperatively through the paracentesis site using a viscoelastic substance, a great deal of posterior resistance may be noted, the anterior chamber may not deepen as much as in a hypotonic eye that does not have malignant glaucoma, and the IOP may rise substantially.

## DIAGNOSIS

The diagnosis of malignant glaucoma is based clinically on the previously mentioned ocular manifestations, and it is made only after ruling out pupillary block, suprachoroidal hemorrhage, serous choroidal effusions, or other causes of a flat anterior chamber. High-resolution ultrasound biomicroscopy can be useful to confirm the diagnosis.<sup>10</sup> It reveals anterior rotation of the ciliary body against the peripheral iris and forward displacement of the posterior chamber intraocular lens, as well as a shallow central anterior chamber, all of which are reversible.

TABLE 10.19.1 Differential Diagnosis of Aqueous Misdirection

Criterion	Malignant Glaucoma	Pupillary Block	Suprachoroidal Hemorrhage	Serous Choroidal Effusions
Intraocular pressure	Normal or elevated	Elevated	Normal or elevated	Low
Anterior chamber depth	Shallow; flat centrally and peripherally	Shallow; flat peripherally but deeper centrally	Shallow; flat centrally and peripherally	Shallow; flat centrally and peripherally
Relief by iridectomy	No	Yes	No	No
Ophthalmoscopy	Choroid and retina flat	Choroid and retina flat	Bullous dark brown or dark red choroidal elevations	Bullous light brown choroidal elevations
Ultrasound biomicroscopy	Anterior rotation of ciliary body and lens with ciliary processes flat against iris, pointing directly anteriorly	Iris bombé with lens in normal position	–	–
B-scan ultrasound	–	–	Smooth, thick, dome-shaped movement with little after-movement	Smooth, thick, dome-shaped membrane with little after-movement
			Heterogeneous low-medium reflective echoes	Echolucent suprachoroidal space, high reflective choroidal thickening
Onset	Intraoperative or early postoperative period Occasionally months to years later	Early postoperative period	Intraoperative or early postoperative period associated with pain, nausea/vomiting	Intraoperative or early postoperative period

DIFFERENTIAL DIAGNOSIS

The most difficult entity to distinguish from malignant glaucoma is pupillary block. Pupillary block should be suspected if iris bombé is present and if the anterior chamber is relatively deeper centrally and shallow to flat peripherally. In contrast, with malignant glaucoma, the anterior chamber is uniformly shallow or flat both centrally and peripherally. Next, the presence or absence of a patent iridectomy must be established. If an iridectomy is not present or not patent, a peripheral iridectomy should be performed. Pupillary block is confirmed if the anterior chamber deepens with an iridectomy. If no relief occurs with iridectomy and ophthalmoscopy or B-scan ultrasonography rules out suprachoroidal hemorrhage or serous choroidal effusion, a diagnosis of malignant glaucoma is made. The distinguishing features of these entities are summarized in Table 10.19.1.

TREATMENT

Medical

The first line of therapy is medical and involves the use of cycloplegics and mydriatics, particularly atropine, as proposed by Chandler and Grant more than 50 years ago.<sup>11,12</sup> Atropine 1% 2–3 times a day is given to move the lens–iris diaphragm posteriorly and relax the ciliary muscle, changing the relationship between the ciliary processes and the vitreous face. Phenylephrine 2.5%, cyclopentolate 1%, and tropicamide 1% may be given every 5 minutes times three as a cycloplegic burst in the office. To decrease aqueous production, topical beta-blockers, oral or topical carbonic anhydrase inhibitors, and α-agonists are used. Osmotic agents such as isosorbide 1.5 mg/kg orally or mannitol 2 g/kg intravenously over a 45-minute period can be used to shrink the vitreous volume. No oral foods or liquids should be given 2 hours before or after the administration of a hyperosmotic agent to avoid reduction in the osmotic effect. The patient is maintained on atropine for a prolonged period with a very slow taper because of the high risk of recurrence. Miotic agents are contraindicated, as they may cause or contribute to malignant glaucoma. Medical therapy is successful in approximately 50% of cases within 4–5 days.<sup>7,11,12</sup>

Laser

The second line of treatment is laser therapy. Neodymium:yttrium–aluminum–garnet (Nd:YAG) laser may be used in aphakic and pseudophakic patients to create a large peripheral iridectomy and capsulectomy with hyaloid rupture to release the trapped aqueous from the vitreous and re-establish normal aqueous flow.<sup>3,13,14</sup> Several openings are made peripherally—that is, not directly behind the lens optic, if an intraocular lens is present.<sup>3,13,15</sup> The placement of the iridectomies should be peripheral, because the underlying etiology is an abnormal relationship between the hyaloid and the ciliary processes.<sup>3,13,14</sup> Peripheral placement will enable anterior migration of the aqueous and maximize the likelihood of resolution of the malignant glaucoma. In addition, transscleral laser cyclophotocoagulation can be used to shrink the ciliary processes and induce posterior rotation of the ciliary processes.<sup>16</sup> Alternatively, direct argon laser treatment can be applied to the ciliary processes through a laser peripheral iridectomy.<sup>15</sup>

If there is corneal–lenticular contact there is the risk of corneal decompensation, therefore the chamber should be reformed by the injection of a viscoelastic substance via a 30-gauge cannula through the original paracentesis at the slit lamp following Nd:YAG laser hyaloidectomy.<sup>1</sup>

Surgery

When medical or laser therapy fails, surgery must be performed. In pseudophakic eyes, vitrectomy surgery is successful in resolving malignant glaucoma in 65%–90% of patients compared to only 25%–50% of phakic patients.<sup>17,18</sup> In phakic eyes, definitive management usually requires phacoemulsification with intraocular lens (IOL) combined with pars plana vitrectomy. The combination of vitrectomy–iridectomy–zonulectomy with phacoemulsification in phakic eyes or without in pseudophakic eyes has shown lower relapse rates compared to vitrectomy alone (*Clinical Management of Malignant Glaucoma*). In pseudophakic eyes, a limited anterior vitrectomy–zonulectomy–iridectomy from either an anterior or pars plana approach can be curative. The key is allowing direct aqueous communication between the anterior chamber and vitreous cavity (Zarnowski) to disrupt the vicious cycle of malignant glaucoma.<sup>17,19–21</sup>

Fellow Eye

There is a high risk of malignant glaucoma in the fellow eye. If a narrow angle is present in the fellow eye, a laser peripheral iridectomy is performed before any other surgical procedures. The risk may be reduced in the fellow eye if the angle remains open and the IOP is normal. Failure to provide prompt therapy to the fellow eye has been reported to result in bilateral blindness. Lens extraction can be considered as a primary procedure before glaucoma surgery.<sup>3</sup> In fact, combined vitrectomy and phacoemulsification with IOL is advocated in high-risk cases.<sup>22</sup>

# Glaucomas Secondary to Abnormalities of the Cornea, Iris, Retina, and Intraocular Tumors

10.20

*Elliott M. Kanner, James C. Tsai*

**Definition:** A diverse group of secondary glaucomas, either open or closed angle, caused by specific abnormalities of the anterior and/or posterior segment. The open-angle varieties include ghost cell hemolytic glaucoma and Schwartz's syndrome. The closed-angle glaucomas include the iridocorneal endothelial syndromes, Axenfeld-Rieger syndrome, epithelial downgrowth and fibrous ingrowth (proliferation), aniridia, and intraocular tumors. Other conditions feature either mixed or nonspecific mechanisms of elevated intraocular pressure, such as the postcorneal transplant and postalkali injury glaucomas.

## Key Features

- Iris abnormalities.
- Previous intraocular surgery.
- Rhegmatogenous retinal detachment.
- Elevated intraocular pressure.
- Ocular tumors.

## GHOST CELL HEMOLYTIC GLAUCOMA

### INTRODUCTION

Lysed red blood cells (RBCs) from vitreous hemorrhage can accumulate in the eye if not properly cleared. Remnants of these partially degraded cells contain very little hemoglobin and are referred to as ghost cells, which can cause blockage of the trabecular meshwork. These denatured erythrocytes develop within 2–4 weeks of a vitreous hemorrhage. Any traumatic event that leads to hemorrhage in the vitreous cavity<sup>1</sup> or, rarely, in the anterior chamber, may result in the formation of ghost cell glaucoma.

### EPIDEMIOLOGY AND PATHOGENESIS

The membrane remnants (ghost cells) have lost their intracellular hemoglobin and appear as khaki-colored cells that are less flexible than normal red blood cells. This loss of pliability results in obstruction of the normal trabecular meshwork pathways and subsequent development of secondary glaucoma. For the remnant RBCs to gain access to the anterior chamber, the hyaloid face or posterior lens capsule must be disrupted (which may occur after surgery).

### OCULAR MANIFESTATIONS

The usual history is a chronic vitreous hemorrhage resulting in a sudden onset of elevated intraocular pressure (IOP). The IOP level may be sufficient to cause corneal edema. The anterior chamber is filled with circulating, small, tan-colored cells that layer in the inferior anterior chamber angle (Fig. 10.20.1). The cellular reaction appears out of proportion to the aqueous flare, and the conjunctiva tends not to be inflamed unless the IOP is elevated markedly. On gonioscopy, the angle appears normal except for the presence of ghost cells layered over the inferior trabecular meshwork.

**Fig. 10.20.1** Ghost Cell Glaucoma. Layered ghost cells in the inferior anterior chamber angle.

### PATHOLOGY

Ghost cells lose their hemoglobin through permeable cell membranes. The cells are nonpliable, having lost their natural biconcavity, and are unable to exit through the trabecular meshwork efficiently. Heinz bodies (denatured hemoglobin) can be found in the cytoplasm.<sup>1</sup>

### TREATMENT

The initial treatment is antiglaucoma medical therapy, followed by intraocular surgery in eyes that are nonresponsive to medical treatment. Irrigation of the anterior chamber and pars plana vitrectomy are the initial surgeries of choice to eliminate the source of degenerative red blood cells. If this proves unsuccessful, glaucoma filtration surgery may be required.

## SCHWARTZ'S SYNDROME

The first description of chronic open-angle glaucoma secondary to rhegmatogenous retinal detachment was presented in 1973 by Schwartz.<sup>2</sup> These patients presented with retinal detachments and increased IOP. The elevated IOP resolved following repair of the retinal detachment. All patients had an apparent anterior chamber inflammatory response.

In 1977 Phelps and Burton surveyed 817 patients who underwent retinal detachment repair.<sup>3</sup> They found 18 patients (2.2%) who fit the criteria for Schwartz's syndrome. At that time, several mechanistic theories were proposed. Schwartz postulated that the associated iridocyclitis causes a trabeculitis that decreases aqueous outflow.<sup>2</sup> Matsuo et al. detected photoreceptor outer segments in the anterior chambers of seven patients who had retinal detachments, a discovery that suggested a connection between the subretinal space and the anterior chamber in this condition.<sup>4</sup>

In 1989, Lambrou et al. injected rod outer segments into the anterior chambers of cats in vivo, which resulted in an average rise in IOP

of 10 mm Hg (1.33 kPa).<sup>5</sup> Electron microscopy revealed occlusion of the intratrabecular spaces by the rod outer segments, with little evidence of inflammatory activity. An interesting observation was that the injected rod outer segments mimicked cells in the anterior chamber,<sup>6</sup> which may represent what Schwartz described as iridocyclitis in his original article.<sup>7</sup>

Davidorf described four cases of retinal detachment with elevated IOP and heavy pigmentation of the trabecular meshwork.<sup>7</sup> The IOP decreased after successful reattachment of the retina in these cases. Regardless of the presumed pathophysiology of Schwartz's syndrome, treatment consists of repair of the retinal detachment. The blocked trabecular meshwork causes an increase in IOP that is resistant to medical therapy. The anterior chamber "inflammation" does not typically respond to conventional medical treatment.

## IRIDOCORNEAL ENDOTHELIAL SYNDROME

### INTRODUCTION

Since the initials ICE fit both the term *iridocorneal endothelial* syndrome and the first letter of each of the three component entities, Yanoff suggested the term *ICE syndrome* in 1979 for this spectrum of clinical and histopathological abnormalities.<sup>8</sup> That term is now the one most commonly used. Historically, the component entities were classified as the iris nevus (Cogan–Reese), Chandler's, and essential (progressive) iris atrophy syndromes.

Collectively, ICE syndrome describes a group of disorders characterized by abnormal corneal endothelium that is responsible for variable degrees of iris atrophy, secondary angle-closure glaucoma in association with characteristic peripheral anterior synechiae (PAS), and corneal edema.

### EPIDEMIOLOGY AND PATHOGENESIS

The condition is sporadic and unilateral but with subclinical irregularities of the corneal endothelium commonly noted in the fellow eye. The syndrome affects individuals between 20 and 50 years of age and occurs more often in women. Glaucoma is present in approximately half of all cases.<sup>9</sup> In a study of 37 cases of ICE syndrome, approximately half (21 cases) were Chandler's syndrome; the other two clinical variations each accounted for about one fourth of all cases.<sup>10</sup> Gonioscopic examination of the angle may not reveal anatomic closure, though the "open appearing angle" may still be functionally closed by the endothelial membrane.

### OCULAR MANIFESTATIONS

Patients present with differing degrees of pain, decreased vision, and abnormal iris appearance. The vision may be decreased from corneal edema, which may be worse in the morning and improve later in the day. Microcystic corneal edema may be present without elevated IOP, especially in the case of Chandler's syndrome. In the advanced stages of the syndrome, symptoms of blurred vision and pain may persist throughout the day. Patients also may present with a chief complaint of an irregular shape or position of the pupil (corectopia), or they may describe a dark spot in the eye, which may represent hole formation (pseudopolyopia) or stromal atrophy of the iris. Various degrees of iris atrophy characterize each of the specific clinical entities.

#### Progressive (Essential) Iris Atrophy

This variation is characterized by severe iris atrophy that results in heterochromia, marked corectopia, ectropion uveae, and pseudopolyopia (hole formation). Iridal hole formation is the hallmark finding of progressive iris atrophy (Fig. 10.20.2).

#### Chandler's Syndrome

This variation shows minimal or no iris stromal atrophy, but mild corectopia may be present. The corneal edema and angle findings are the predominant and typical features (Fig. 10.20.3).

#### Iris–Nevus Syndrome (Cogan–Reese Syndrome)

The extent of iris atrophy tends to be variable and less severe. Tan, pedunculated nodules may appear on the anterior iris surface. The entire spectrum of corneal and other iris defects may occur in this variant.

Fig. 10.20.2 Hole Formation in Progressive Iris Atrophy.

Fig. 10.20.3 Corneal Edema and Iris Findings Are Typical of Chandler's Syndrome.

### PATHOLOGY

The common pathological feature is the appearance of the corneal endothelium, which appears as a fine, hammered silver material, similar to the guttae seen in Fuchs' corneal endothelial dystrophy.<sup>11</sup> Descemet's membrane is normal, but the endothelial cells are abnormal. These endothelial cells take on characteristics of epithelial cells. With electron microscopy, this endothelial layer varies in thickness from a single layer to multiple layers (while normal endothelial cells are invariably a monolayer).<sup>12,13</sup> The endothelial cell layer can vary in thickness in different areas. The cells appear to have the potential to move, as demonstrated by filopodial cytoplasmic processes and cytoplasmic actin. The morphology of the endothelium suggests a widespread state of high metabolic activity.<sup>14,15</sup> These changes and endothelial dysfunction result directly in the corneal edema. The anterior chamber angle may also show high PAS that extend beyond Schwalbe's line. The high PAS are caused by contraction of the endothelial cell layer and surrounding tissues, which extend from the peripheral cornea over the trabecular meshwork and iris. These membranes can contract and cause progressive angle closure. As noted earlier, secondary glaucoma with an open angle may also occur when the endothelial membrane covers the trabecular meshwork without observable evidence of synechiae formation.

The extent of iris abnormalities differentiates the specific clinical variations. When the endothelial cell layer contracts over the iris, this distorts the iris directly, causing holes (Fig. 10.20.4).<sup>16</sup> Hole formation may be associated with ischemia of the iris, as suggested by fluorescein angiography. In Cogan–Reese syndrome, the pigmented, pedunculated nodules seen

**Fig. 10.20.4 Iridocorneal Endothelial Syndrome.** Histological section of an eye that had essential (progressive) iris atrophy shows a peripheral synechia (P), various degrees of degeneration and loss of the central iris stroma, and total loss of the central iris pigment epithelium (IP). (C, Cornea; CB, ciliary body; IR, iris root; L, lens.) (With permission from Yanoff M, Fine BS. Ocular pathology. London: Mosby; 1996.)

are composed of underlying iris stroma pinched off by abnormal cellular membrane.<sup>17</sup>

A viral cause has been postulated for the pathophysiological mechanism of ICE syndrome. Epstein-Barr and herpes simplex viruses have been found serologically in ICE patients.<sup>12,18</sup> Lymphocytes were found on a sample of the corneal endothelium of an ICE patient, suggesting chronic inflammation.

## TREATMENT

A diagnosis of ICE syndrome must be considered in younger patients who have unilateral angle-closure glaucoma and can be confirmed by specular or confocal microscopy. Aqueous suppressant medications tend to be effective in controlling the IOP, whereas prostaglandin analogs and other outflow-associated medications are less effective. Corneal edema may often be controlled using hypertonic saline solutions. Reduction of the elevated IOP may lessen the degree of corneal edema. If the IOP level remains uncontrolled despite medical treatment, filtration surgery may be indicated, though late surgical failures have been reported secondary to endothelialization of the fistular opening.<sup>19,20</sup> These endothelial obstructions of the fistula may be reopened successfully using the neodymium:yttrium-aluminum-garnet (Nd:YAG) laser. In a study of 83 patients who had ICE syndrome, the success rates of initial trabeculectomy operations at 1 and 3 years were both 58%,<sup>20</sup> and those of second and third operations at 1-year intervals were both 58%.<sup>13</sup> Glaucoma tube shunt procedures are indicated for cases refractory to the previously mentioned treatments and more recently have been used as the primary procedure.<sup>21</sup>

## AXENFELD-RIEGER SYNDROME

Axenfeld-Rieger (A-R) syndrome represents a rare spectrum of developmental disorders involving abnormalities of both ocular and extraocular structures derived from the neural crest.<sup>22</sup> The term *anterior cleavage syndrome* was used in the past,<sup>23</sup> but it incorrectly reflects the development in this syndrome. All clinical variations of this syndrome are now referred to as Axenfeld-Rieger syndrome (rather than the individual component syndromes).

## EPIDEMIOLOGY AND PATHOGENESIS

A-R syndrome involves the anterior segment bilaterally and is associated with secondary glaucoma due to arrested angle development in about 50% of cases. A-R syndrome is a rare, autosomal dominant inherited disorder. Shields<sup>24</sup> postulated that the developmental arrest late in gestation results in primordial endothelium being retained over parts of the iris and anterior chamber angle. Contraction of this layer causes iris stromal thinning, corectopia, and hole formation. With contraction, the anterior uvea is hindered from posterior migration, which results in a high insertion of the iris into the anterior chamber angle.<sup>22</sup> Several mutations are associated with A-R, including *PITX2*, *FOXC1*, and *PAX6*.<sup>25</sup> The affected anterior segment structures are primarily of neural crest derivation. The most common extraocular defects involve dentition and facial bones.

## OCULAR MANIFESTATIONS

The typical abnormality of the cornea is an anteriorly displaced Schwalbe's line (posterior embryotoxon) that appears as a white ring on the posterior cornea near the limbus. The ring tends to be more common temporally and rarely involves all 360°. An anteriorly displaced Schwalbe's line occurs in 8%–15%<sup>26,27</sup> of the general population and may not always be present with A-R syndrome. On gonioscopy, thread-like PAS extending to the posterior embryotoxon may obscure the angle. Iris defects ranging from stromal thinning to actual hole formation, corectopia, and ectropion uveae may occur.

## SYSTEMIC ASSOCIATIONS

Developmental defects associated with A-R syndrome most commonly involve dentition and facial bones. Microdontia (peg-like incisors), hypodontia (decreased number of evenly spaced teeth), and anodontia (focal absence of teeth) are noted most commonly.<sup>23,27</sup> The facial abnormalities include maxillary hypoplasia and a protruding lower lid. Telecanthus, hypertelorism, and primary empty-sella syndrome have also been documented with A-R syndrome.<sup>22,28,29</sup>

## PATHOLOGY

The peripheral cornea characteristically exhibits an anteriorly displaced Schwalbe's line. This posterior embryotoxon shows a cellular monolayer with basement membrane that covers dense collagen.<sup>22,27</sup> The iridocorneal strands tend to be iris stroma mixed with the aforementioned cellular monolayer. This cellular membrane also may extend over the iris surface, which distorts the iris, creates iris stromal thinning, and results in actual hole formation and corectopia as it contracts.

## TREATMENT

Topical medications that decrease aqueous flow (beta-blockers, carbonic anhydrase inhibitors, and short-term use of  $\alpha$ -agonists) are more effective than outflow facilitators (prostaglandin analogs, pilocarpine). Surgical intervention may be goniotomy or trabeculectomy.<sup>30,31</sup> The procedure of choice in A-R syndrome is usually trabeculectomy with the adjunctive use of antimetabolites.<sup>32,33</sup> If the initial surgical treatment fails, glaucoma tube shunt procedures may be utilized.<sup>34</sup>

## EPITHELIAL DOWNGROWTH AND FIBROUS INGROWTH (PROLIFERATION)

### INTRODUCTION

Unlike ICE syndrome, epithelial downgrowth/fibrous ingrowth results from the access of epithelial/fibrous cells into the anterior chamber. Epithelial/fibrous cells entering through an insufficiently closed wound usually cause these conditions.<sup>35</sup> Fortunately, with advancements in microsurgical techniques (e.g., improved wound closure), the incidence of these entities has been reduced greatly.

## EPIDEMIOLOGY AND PATHOGENESIS

The incidence of epithelial downgrowth and fibrous ingrowth has declined greatly over the years with the advent of small-incision surgery. The prevalence of epithelial downgrowth occurred in the range of 0.12%–0.6% following intracapsular cataract surgery.<sup>36–38</sup> While previously more common after cataract surgery, epithelial downgrowth is now more commonly seen after penetrating keratoplasty,<sup>39–41</sup> ocular trauma, and glaucoma filtration surgery.<sup>42,43</sup> Fibrous ingrowth is more prevalent than epithelial downgrowth, progresses more slowly, and is often self-limited. Epithelial downgrowth and fibrous ingrowth can occur simultaneously.<sup>36</sup> Prolonged ocular inflammation is a major risk factor for epithelial and fibrous proliferation.<sup>44</sup> Other risk factors appear to be wound dehiscence, delayed closure of the wound postoperatively, and stripping of Descemet's layer.<sup>45,46</sup>

Normal postoperative healing of the corneal scleral wound requires invasion of connective tissue to the inner margin of the wound and formation of a fibrous plug. By the second week, the inner wound is usually covered by endothelium. Contact inhibition stops the movement of endothelium.<sup>47,48</sup> When the endothelium fails to close this defect, epithelial and

**Fig. 10.20.5** Translucent, Nonvascular, Anterior Chamber Epithelial Cyst.

**Fig. 10.20.6** Grayish, Sheet-Like Epithelial Ingrowth With Rolled Edges.

fibrous proliferation can occur. Thus an abnormality in the corneal endothelium is also a risk factor. Posterior limbal incisions may be more commonly associated with fibrous ingrowth, whereas anterior limbal incisions may be associated with epithelial downgrowth.<sup>44</sup> Small incisional cataract surgery has minimized the importance of such distinctions. Other proposed risk factors for fibrous and epithelial proliferation are fornix-based conjunctival flaps, intraocular use of surgical instruments on the conjunctiva,<sup>49</sup> and use of intracameral anticoagulant therapy.<sup>50</sup>

## OCULAR MANIFESTATIONS

Epithelial proliferation may be present in three forms: “pearl” tumors of the iris, epithelial cysts, and epithelial ingrowth. Epithelial cysts and epithelial ingrowth often cause secondary glaucoma. Epithelial cysts appear as translucent, nonvascular anterior chamber cysts that originate from surgical or traumatic wounds (Fig. 10.20.5). Epithelial ingrowth presents as a grayish, sheet-like growth with rolled edges on the posterior surface of the cornea (Fig. 10.20.6), trabecular meshwork, iris, and ciliary body. It is often associated with wound incarceration, wound gape, ocular inflammation, band keratopathy,<sup>41,51</sup> and corneal edema. The degree of ingrowth can be very specifically detected by the characteristic whitening on application of the argon laser (Fig. 10.20.7).<sup>52</sup> Specular and confocal microscopy provide other means of diagnosis by direct visualization of epithelial cells.<sup>53</sup>

Unlike epithelial proliferation, fibrous ingrowth is slow to progress and may be self-limited. A common cause of corneal graft failure, fibrous ingrowth appears as a thick, gray-white, vascular, retrocorneal membrane with an irregular scalloped border reminiscent of woven cloth.<sup>54</sup> The ingrowth often involves the angle, which results in the formation of PAS and the destruction of the trabecular meshwork. The resultant secondary angle-closure glaucoma is a frequent complication and is often difficult to control medically.

**Fig. 10.20.7** Epithelial Iris Cyst and Downgrowth. (A) Scanning electron microscopy shows a sheet of epithelium that covers the trabecular meshwork, anterior face of the ciliary body, anterior iris, and pupillary margin. (B) Epithelium lines the posterior cornea, anterior chamber angle, and peripheral iris and extends onto the vitreous posteriorly in a surgically aphakic eye. (C) Detection of epithelial downgrowth by application of argon laser to the iris. (A–B, With permission from Yanoff M, Fine BS. Ocular pathology. London: Mosby; 1996.)

**BOX 10.20.1 Management Options of Noncystic/Diffuse Epithelial Proliferation**

- Freezing the involved corneal surface to close the wound gape or fistula
- Swabbing the involved corneal surface with absolute ethanol
- Resecting the posterior membrane<sup>60</sup>
- Intracameral injection of 5-fluorouracil<sup>161</sup>

**PATHOLOGY**

Epithelial downgrowth consists of a multilayered membrane composed of nonkeratinized, stratified, squamous epithelium that has surface microvilli; wide intercellular borders with occasional hemidesmosomes attached to a subepithelial connective tissue layer; and epithelial cells of uneven sizes and shapes.<sup>55,56</sup> This epithelial sheet lacks blood vessels and shows multiple tonofilaments at its leading edge (see Fig. 10.20.7).<sup>57</sup> The underlying structures in contact with the epithelial sheet undergo disorganization and destruction.

**TREATMENT**

Management of epithelial cysts includes observation until complications are observed. Numerous approaches have been used to excise epithelial cysts, but currently a wide excision of the intact cyst is preferred. If the cyst is adherent to any intraocular structures, it may be collapsed by aspiration before excision.<sup>58</sup> Photocoagulation of epithelial cysts, a less invasive procedure than surgical removal, has been performed successfully.<sup>59</sup> Photocoagulation is less effective when the cyst is nonpigmented or adherent to underlying structures. The management options for noncystic/diffuse epithelial proliferation are listed in Box 10.20.1.

Management of glaucoma is a difficult challenge and has a high failure rate using traditional filtration surgery techniques. Glaucoma drainage tube implants have been shown to be the most effective procedure, with both fibrous and epithelial ingrowth.<sup>34,62</sup> Cycloablation is used only when other treatment modalities fail.

**ANIRIDIA****INTRODUCTION**

Aniridia is a rare, bilateral, hereditary absence of the iris. The condition rarely occurs in its pure form and usually presents with a rudimentary stump of iris.

**EPIDEMIOLOGY AND PATHOGENESIS**

Aniridia is seen in approximately 1.8/100 000 live births.<sup>63</sup> Three phenotypes are recognized, of which autosomal dominant aniridia is the most common; it is present in approximately 85% of all cases and is not associated with any other systemic manifestations. The second type is congenital sporadic aniridia, found in association with Wilms' tumor (nephroblastoma), genitourinary anomalies, and intellectual disability (Miller's syndrome). The second type has been labeled WAGR syndrome (for Wilms' tumor, aniridia, genitourinary anomalies, retardation), is linked with partial deletions of the short arm of chromosome 11 (11p13), and accounts for approximately 13% of all aniridias. Autosomal recessive aniridia is the third genetic type; it is seen in approximately 2% of all cases and is associated with cerebellar ataxia and mental retardation (Gillespie's syndrome).<sup>64</sup> Hereditary aniridia is associated with the *PAX6* gene.<sup>65</sup>

Different theories have been developed to explain the pathogenesis of aniridia. Some researchers consider it a subtype of coloboma. In addition, some aniridias are associated with hypoplastic discs and the absence of iris musculature, on the basis of which investigators have proposed mesodermal and neuroectodermal theories, respectively. Glaucoma develops in about 50% of patients who have aniridia.<sup>66</sup> Glaucoma is rare in newborns; it is usually seen after the second decade of life, as anatomic changes occur in the angle secondary to contracture of peripheral iris strands.<sup>67</sup> These iris strands bridge the space between the iris stump and trabecular meshwork, resulting in angle-closure glaucoma. In addition, goniodysgenesis is noted in some cases.

**OCULAR MANIFESTATIONS**

The clinical manifestations of aniridia include photophobia related to the extent of iris involvement. Pendular nystagmus, decreased vision, amblyopia, and strabismus are seen secondary to foveal and optic nerve head hypoplasia. Bilateral ptosis also may occur in aniridia. With gonioscopy, the iris appears as a rudimentary stump with fibers that bridge the angle. This rudimentary iris leaflet appears to be pulled forward by iris strands, which results in posterior synechiae formation and subsequent angle-closure glaucoma. In addition to the anterior segment changes, findings in the posterior segment may include foveal and optic nerve head hypoplasia and choroidal coloboma. Lenticular changes include cataract, ectopia lentis, microphakia, and persistent pupillary membranes. Microcornea<sup>68</sup> and corneal opacifications also have been observed in aniridic patients. The corneal opacification is often associated with a fine, vascular network and pannus formation.<sup>69</sup>

**SYSTEMIC ASSOCIATIONS**

Wilms' tumor (nephroblastoma) is found in association with aniridia in Miller's syndrome; 25%–33% of patients who have sporadic aniridia develop Wilms' tumor. In addition to Wilms' tumor, severe mental retardation, genitourinary anomalies, craniofacial dysmorphism, and hemihypertrophy can occur.<sup>62</sup> In Gillespie's syndrome, intellectual disability and cerebellar ataxia are seen.

**PATHOLOGY**

Arrestment of the neuroectodermal tissue is the most striking histopathological feature of this condition. With histological examination, a small stump of iris that lacks iris musculature may be observed. The iris remnant appears continuous with the trabecular meshwork. Glaucoma in Miller's syndrome may develop secondary to angle anomalies, which include dysgenesis of the trabecular meshwork and Schlemm's canal.<sup>63</sup>

**TREATMENT**

Glaucoma and its surgical complications are the main causes of blindness in patients with aniridia. Surgery is often required by age 20 for IOP control.<sup>63,70,71</sup> A prophylactic modified goniotomy has been advocated to prevent this secondary glaucoma in certain young patients with aniridia.<sup>72,73</sup>

**TUMORS AND GLAUCOMA****INTRODUCTION**

A variety of intratumors may cause unilateral glaucoma; the most common ones associated with glaucoma include primary melanomas, metastases, and retinoblastomas. The mechanism of glaucoma development varies with the location, type, and size of the tumor. Choroidal melanomas and other choroidal and retinal tumors close the angle by a mass effect by shifting the lens–iris diaphragm forward with angle closure. Inflammation caused by necrotic tumors can cause posterior synechiae, which can exacerbate this angle closure through a pupillary block mechanism. Neovascularization can be caused by choroidal melanomas, medulloepitheliomas, and retinoblastomas. Liberated tumor cells can also obstruct aqueous outflow.

**EPIDEMIOLOGY AND PATHOGENESIS**

In 1987, Shields et al.<sup>74</sup> studied 2704 eyes that had intraocular tumors, of which 5% were found to have IOP elevation secondary to the tumor. The most common tumor in adults to result in glaucoma was malignant uveal melanoma.<sup>75–79</sup> Direct infiltration of the angle was the most common cause of increased IOP. The trabecular meshwork can also be obstructed by pigment, tumor, or inflammatory cells. Shields et al.<sup>74</sup> found glaucoma in 7 of 102 eyes that had iris melanoma. Iris melanocytomas are rare and have a predisposition to release pigment into the anterior chamber, which causes a secondary open-angle glaucoma.<sup>80</sup> Ciliary body melanomas may present with increased IOP secondary to a variety of mechanisms.<sup>76</sup>

Shields et al.<sup>74</sup> reported that 16 of 96 eyes that had ciliary body melanomas also had associated glaucoma. Medulloepithelioma (diktyoma) is a tumor of the nonpigmented ciliary epithelium and usually presents in childhood as a cystic or solid tumor, and in one study, about 50% of these eyes presented with glaucoma, with neovascularization as the most common

cause of glaucoma.<sup>76</sup> Mechanical displacement of the angle, direct invasion of the angle, and one case of recurrent hyphema also caused glaucoma.<sup>77</sup>

Retinoblastoma is the most common malignant intraocular tumor of childhood. Approximately 1 in 14 000–20 000 newborns have retinoblastoma, and 30%–35% of cases occur bilaterally, with no sex or race predisposition. Glaucoma secondary to retinoblastoma has an incidence of 2%–22%.<sup>74,81</sup> Neovascular glaucoma secondary to retinal ischemia is the most common mechanism (73%).<sup>74</sup> The second most common cause of glaucoma in these eyes is anterior displacement of the lens–iris diaphragm.

Metastatic tumors in the uvea are usually posterior. The most common sites of origin are breasts in women and lungs in men.<sup>80</sup> In contrast to iris and ciliary body metastases, metastatic tumors to the choroid show only about a 2% incidence of glaucoma. The main presentation of glaucoma results from a forward shift of the lens–iris diaphragm secondary to non-rhegmatogenous retinal detachment.<sup>81</sup> Glaucoma is associated with 64% of iris metastases and 67% of ciliary body metastases.<sup>74</sup> Elevated IOP is seen in patients with these tumors, usually from localized blockage of the trabecular meshwork by released tumor cells.<sup>81</sup>

## OCULAR MANIFESTATIONS

The clinical presentation of glaucoma that arises from intraocular tumors is dependent on the mechanism of inducement. Glaucoma secondary to tumors may present as secondary angle-closure glaucoma by a posterior-push mechanism or an anterior-pull mechanism. Other mechanisms include those of secondary open-angle glaucoma.

## PATHOLOGY

Iris melanoma usually appears as a well-circumscribed, variably pigmented, fixed, or slow-growing tumor that may eventually invade the trabecular meshwork. The tumor is composed of spindle-shaped cells with occasional epithelioid cells.<sup>81</sup> Ciliary body melanoma appears as a circumscribed mass that replaces the ciliary body. Choroidal melanoma appears as a variably pigmented mass that may result in a secondary nonrhegmatogenous retinal detachment. As the tumor breaches Bruch's membrane it can form the characteristic “mushroom” shape. Melanocytoma appears as a brown or black mass that may be well circumscribed<sup>80</sup> and usually occurs at the optic disc but may arise anywhere in the uvea. Necrotic areas are present within the mass, which may result in fragmentation and liberation of tumor cells into the angle.<sup>81</sup>

Iris and ciliary body metastases usually have poor differentiation, which makes determination of the primary site difficult. Choroidal metastases are ill-defined, relatively elevated, or diffuse lesions, often associated with serous or choroidal retinal detachment. The lesions may present with a brown discoloration secondary to overlying pigment or with a gray to yellow–cream color. Retinoblastoma appears as a chalky white mass within the globe and is composed of neuroblastic cells; areas of calcification and necrosis are common findings. The differentiated tumors are characterized by highly organized Flexner–Wintersteiner rosettes.<sup>80</sup> Medulloepithelioma is an embryonic tumor that usually occurs in the ciliary body. The tumor appears as a yellow–pink solid or cystic mass and may contain rosettes. Medulloepithelioma has two types of presentation: the nonteratoid type is composed of nonpigmented epithelium and the teratoid type shows two different germ layers (i.e., cartilage and skeletal muscle).<sup>81</sup>

## TREATMENT

Malignant ocular tumors are often enucleated as the definitive management. Traditional filtration techniques run the risk that tumor cells may be seeded to extraocular areas even after treatment with radiation. Secondary glaucoma from benign tumors can be managed medically and with traditional filtration surgeries. Proper diagnosis of tumors usually is made clinically. Fluorescein angiography and ultrasonography (e.g., A-scan, B-scan, ultrasound microscopy [UBM]) help in the detection and diagnosis of intraocular tumors. In some patients, a fine-needle biopsy, aqueous aspiration, or biopsy is needed for diagnosis.

## PENETRATING KERATOPLASTY

### INTRODUCTION

Secondary glaucoma is a common complication of penetrating keratoplasty and occurs with increased frequency in aphakic and pseudophakic

### BOX 10.20.2 Mechanisms of Secondary Glaucoma Formation

- Wound distortion of trabecular meshwork
- Fibrous ingrowth
- Postoperative inflammation
- Chronic angle closure
- Viscoelastic
- Corticosteroid induced
- Pre-existing conditions

patients<sup>81</sup> and in repeat corneal grafts. The different mechanisms of secondary glaucoma formation are listed in Box 10.20.2. Distortion of the angle, chronic angle closure, and a predisposition before surgery are the most common causes.

## EPIDEMIOLOGY AND PATHOGENESIS

Improved surgical and storage techniques have resulted in a large increase in the number of corneal transplants being done. Penetrating keratoplasty is one of the most successful of all transplants, with a 1-year survival rate of 80%–90%.<sup>82</sup> Postkeratoplasty glaucoma occurs more frequently in patients affected by pre-existing glaucoma. Aphakic and pseudophakic bullous keratopathies are the most common indications for penetrating keratoplasty, at rates of 20%–70% and 18%–53%, respectively.<sup>83</sup> One study indicated no early or late glaucoma in patients who had penetrating keratoplasty for keratoconus and a less than 2% incidence in patients who had Fuchs' corneal endothelial dystrophy treated with penetrating keratoplasty.<sup>84</sup>

## OCULAR MANIFESTATIONS

Graft clarity is reduced significantly when postkeratoplasty glaucoma is present.<sup>85,86</sup> Glaucoma affects the cornea directly and the visual potential by causing optic neuropathy. In early postkeratoplasty glaucoma, epithelial edema is found along with stromal thinning and compression. Such findings are noted before endothelial damage occurs.<sup>87</sup> Progressive angle closure from peripheral synechiae formation is an early sign of impending glaucoma in postkeratoplasty patients. Some studies have demonstrated the presence of PAS in all eyes with elevated IOP after keratoplasty.<sup>88</sup> A major study in which routine gonioscopy was conducted, however, concluded that progressive synechial closure was a plausible explanation for only 14% of eyes that had elevated IOP.<sup>89</sup>

As topical corticosteroids are the mainstay of rejection treatment in corneal transplants, this can also be a cause of increased IOP in susceptible individuals. The use of potent corticosteroids at frequent intervals was reported to reduce the rates of early IOP elevation.<sup>87</sup> In contrast, certain cases of IOP elevation may be related to corticosteroid responders. Following corticosteroid use, reported rates of secondary IOP are increased from 5%–60%.<sup>88–92</sup> This fact outlines the double-edged sword of corticosteroids: the necessity for postkeratoplasty inflammation and potential for postkeratoplasty glaucoma. As we gain experience with other immunosuppressants and their effects on the eye in uveitis, these agents may play a role as corticosteroid-sparing agents in corneal transplants.

## TREATMENT

Treatment modalities for postkeratoplasty glaucoma include medical therapy, trabeculectomy, glaucoma tube shunt procedures, and cyclodestructive procedures. The initial treatment of choice is medical therapy. However, in the presence of significant synechial closure, drugs that influence outflow facility (i.e., miotics) may have limited action. Similarly, the role of prostaglandin analogs in this type of glaucoma and their influence on graft survival and graft clarity remain uncertain. Dorzolamide has been shown to decrease corneal endothelial function and to increase corneal thickness, and reported cases of graft failure have been attributed to its use.<sup>93</sup>

Glaucoma drainage implants (e.g., Ahmed, Krupin, Molteno, Baerveldt, Schocket) have been useful in controlling IOP among patients who have had difficult previous surgeries.<sup>94</sup> In one study, 29% of patients progressed to failure after Molteno implantation and 20% after insertion of Schocket tube.<sup>95</sup> Long-term studies of glaucoma implants have shown that even in cases with well-controlled glaucoma there is an increase in the failure rate of the corneal graft (75% failure at 2 years, with more than 63% having

well-controlled glaucoma).<sup>96</sup> Placement of the shunt implant through the pars plana may also improve graft survival.

Filtration surgery shows success rates of 27%–80%.<sup>89,95,97–99</sup> Aphakic eyes have a lower success rate than do pseudophakic or phakic eyes. Graft failure at 3 years after trabeculectomy is in the range of 11%–20%.<sup>89,98</sup> Cyclodestructive procedures can lower IOP effectively after penetrating keratoplasty. Laser cyclophotoablation is used in preference to cyclocryotherapy because of its reduced side effects and improved visual result. The reported success rate for laser cyclophotoablation is 50%–100%. Graft failure has been reported with laser cyclophotoablation.<sup>98,100,101</sup>

## ALKALI CHEMICAL TRAUMA

### INTRODUCTION

In the acute setting of a patient who has an alkali burn, glaucoma may be overlooked as a complication. It occurs in the acute and late settings with a possible intermediate period of hypotony secondary to ciliary body damage. Secondary glaucoma occurs more often in association with alkali burns than with acidic burns.

### EPIDEMIOLOGY AND PATHOGENESIS

Alkali can cause severe damage to ocular tissues as a result of the saponification of fatty acids in tissue, which allows deep penetration and damage. In contrast, acidic chemicals have a tendency to coagulate tissue proteins, and the layer of precipitated protein helps buffer and limit the acid's penetration through the cornea. Different mechanisms have been postulated for each phase of IOP elevation. The initial pressure elevation may be secondary to tissue shrinkage of the outer coats of the eye<sup>102</sup> or to prostaglandin release that increases uveal blood flow.<sup>103</sup> The intermediate and late phases show changes in the eye as part of the body's response. In these phases, trabecular damage, PAS, and secondary pupillary block are possible mechanisms for the development of glaucoma.

### OCULAR MANIFESTATIONS

Damage to the cornea may be widespread and progressive. Epithelial disintegration may be followed by stromal ulcerations and perforation. Measurement of IOP in eyes that have extensive corneal damage may be difficult using Goldmann applanation tonometry. A Tono-Pen or pneumotonometer may be more accurate. Gonioscopy may be difficult in these patients because of corneal opacification, in which case ultrasound examination may be necessary to visualize the extent of optic nerve cupping and retinal damage. Later in the disease process, symblepharon formation of the palpebral conjunctiva may obliterate the fornices.

## PATHOLOGY

After exposure to an alkaline chemical, the corneal keratocytes rapidly coagulate to leave devitalized corneal stroma. The bulk of the corneal mucopolysaccharide ground substance also is destroyed, which is followed by collagen fiber swelling. Anterior segment shrinkage or prostaglandin-mediated inflammation may contribute to the IOP elevation. Inflammation will cause PAS, which also contributes. Intraocular lens damage may result in cataract formation, and the associated lens swelling may result in secondary phacomorphic glaucoma.

### TREATMENT

Immediate ocular irrigation is needed to remove the chemical from the corneal surface and fornices. Neutralization of an acid with a base causes thermal reaction, which will worsen injury. The management of increased IOP in the early phase is pharmacological. Miotics and prostaglandin analogs should be used cautiously because they may increase intraocular inflammation. Anti-inflammatory medications and cycloplegics are important during the first week; topical corticosteroids are administered with caution because of their potential effect on corneal stromal melting.<sup>104</sup> Conventional medical and surgical therapies are used for the later phases of IOP elevation associated with chemical trauma.

# Congenital Glaucoma

James D. Brandt, Stuart W. Tompson, Yao Liu

# 10.21

**Definition:** Glaucoma in children less than 2 years of age can be subdivided into (1) primary congenital glaucoma, which is the result of isolated, abnormal development of the anterior chamber angle structures; and (2) secondary congenital glaucomas, either following infantile cataract surgery or those associated with ocular or systemic syndromes.

## Key Features

- Elevated intraocular pressure.
- Glaucomatous optic atrophy.
- Ocular enlargement (“buphthalmos”).

## Associated Features

- Corneal edema.
- Haab’s striae.
- Photophobia.
- Tearing.
- Amblyopia.

## INTRODUCTION

Although clinicians commonly group together all the various forms of “congenital” glaucoma, primary congenital glaucoma (PCG) is the term properly reserved for glaucoma arising due to an isolated developmental defect of the anterior chamber angle structures. PCG is exceedingly rare, and few ophthalmologists will ever make the initial diagnosis of the disease. Nonetheless, most ophthalmologists will encounter the wide variety of secondary glaucomas seen in this age group, especially following surgery for congenital cataract. In this chapter, the reader is provided with a basic understanding of how the various forms of glaucoma can present in infants and young children along with their differential diagnosis and treatment options.

## EPIDEMIOLOGY AND PATHOGENESIS

### Primary Congenital Glaucoma (PCG)

The incidence of primary congenital glaucoma is between 1 in 10 000 and 1 in 15 000 live births in the heterogeneous population of the United States. In other countries, the published series range from a low of 1 in 30 000 in Northern Ireland<sup>1</sup> to a high of 1 in 2500 in Saudi Arabia<sup>2</sup> and 1 in 1250 among Roma families in Romania.<sup>3</sup> Primary congenital glaucoma is bilateral in up to 80% of larger case series; in North America and Europe it is more common in boys, whereas in Japan it is more common in girls.<sup>4,5</sup> The varied incidence among different populations and the increased incidence in consanguineous populations suggests a strong genetic component to the disease. Most new cases (about 90%) of primary congenital glaucoma are sporadic. However, in the remaining 10% there appears to be a strong familial component; penetrance of the defect ranges from 40%–100%.

The pathophysiology and molecular etiology underlying primary congenital glaucoma remains elusive in most cases. However, five regions of the genome termed GLC3A through GLC3E are strongly associated with the disease. The GLC3A locus (OMIM 231300) harbors the cytochrome P450 1B1 (*CYP1B1*) gene, in which homozygous or compound heterozygous loss-of-function mutations are the most common cause of autosomal

recessive primary congenital glaucoma worldwide, particularly in populations with a high prevalence of consanguinity.<sup>6,7</sup> *CYP1B1* protein is required for normal oxidative homeostasis within the eye, and loss of its enzymatic activity can result in an abnormal ultrastructural organization and function of the trabecular meshwork.<sup>8</sup> At the present time, no pathogenic disease-causing mutations have been identified within the GLC3B (OMIM 600975) and GLC3C (OMIM 613085) regions of the genome, although they have been associated with primary congenital glaucoma.<sup>9,10</sup> At the GLC3D (OMIM 613086) locus, autosomal recessive primary congenital glaucoma disease is caused by homozygous or compound heterozygous loss-of-function mutations in the *LTBP2* gene.<sup>11,12</sup> *LTBP2* is an extracellular matrix protein that has roles in cell adhesion and serves as a structural component of microfibrils to confer tissue elasticity. In the eye, *LTBP2* protein localizes to the trabecular meshwork and the ciliary body, where it is essential for normal development of the anterior chamber.<sup>11</sup> Recently, the dogma that primary congenital glaucoma disease always follows an autosomal recessive inheritance pattern was demonstrated to not always hold true. In approximately 4% of primary congenital glaucoma cases, heterozygous loss-of-function mutations in the gene encoding *TEK* (the GLC3E locus, OMIM 617272) cause autosomal dominant disease with variable expressivity.<sup>13</sup> Mice haploinsufficient for *Tek* develop a severely hypomorphic Schlemm’s canal with a variable number of focal narrowings that directly correlates with increased intraocular pressure (IOP). The stochastic severity of outflow pathway malformation provides an explanation for the variable expressivity observed in human families, such as parent-to-child transmission of unilateral disease, and mutation-carrying family members with later onset disease (juvenile and primary open-angle glaucoma). Currently, the molecular basis of disease remains unsolved for approximately 75% of nonconsanguineous primary congenital glaucoma families, but recent advances in exome and whole genome sequencing should expedite the discovery and characterization of additional primary congenital glaucoma-associating genes.

In the early twentieth century, Barkan postulated that a thin, impermeable membrane covered the anterior chamber angle structures and impeded aqueous humor outflow.<sup>14</sup> This hypothesized structure explained why goniotomy, the operation he developed, was so successful in cases of infantile glaucoma. Barkan’s membrane, as the structure became known, has never been confirmed on light or electron microscopy, despite numerous attempts. Some observers have described a compaction of trabecular meshwork that might appear clinically as a continuous membrane.<sup>15</sup> A broad spectrum of anterior chamber “cleavage” disorders<sup>16</sup> often are associated with infantile glaucoma, which suggests that the principal defect in primary congenital glaucoma is a failure of one or more steps in the normal development of the anterior chamber angle.

### Glaucoma Following Cataract Surgery

Taken as a group, the secondary congenital glaucomas of childhood are far more commonly encountered than primary congenital glaucoma. Most common are the early and later onset forms of glaucoma following cataract surgery (GFCS) in infancy. More than half of children who have undergone lens extraction eventually develop ocular hypertension or glaucoma.<sup>17</sup> The Infant Aphakia Treatment Study reported a 12% incidence of glaucoma-related adverse events at 1 year, which increased to 18% by 5-year follow-up.<sup>18,19</sup>

The underlying cause of childhood glaucoma following cataract extraction remains unknown but is almost certainly multifactorial. Rabiah reported that in a case series of 570 eyes with a minimum of 5 years of follow-up, patients who underwent cataract surgery earlier in life, and those with microcornea, had a much higher risk of glaucoma.<sup>20</sup> Mataftsi and colleagues performed an individual patient meta-analysis on 470 patients

and found a similar incidence of glaucoma (17% at a median of 4.3-year follow-up) and an increased risk of glaucoma with younger age.<sup>21</sup> These findings concurred with results from the Infant Aphakia Treatment Study, which also found an increased risk of glaucoma in patients who underwent additional procedures after cataract surgery.<sup>12</sup> It remains unknown whether primary intraocular lens implantation (versus aphakia) is protective.<sup>19</sup> Walton examined 65 children, most of whom presented with glaucoma two or more years after lensectomy.<sup>22</sup> Preoperative gonioscopy revealed no consistent angle defect, but postoperative gonioscopy revealed a near constant (96%) filtration-angle deformity he characterized as blockage of the posterior trabecular meshwork with pigment and synechiae. Many clinicians familiar with this scenario believe that retained lens material is one risk factor for glaucoma that follows pediatric cataract extraction; another is the presence of a small cornea.<sup>19,20</sup> Parks and colleagues described a secondary glaucoma risk of 15% in their cohort of 174 eyes<sup>23</sup>; only 2.9% of eyes that had normal corneal diameters developed glaucoma, whereas 32% of eyes that had corneal diameters <10 mm developed the disease. The presence of both a cataract and a small cornea almost certainly indicates an abnormality that occurred during ocular development; perhaps cataract surgery unmasks a marginally functional and mal-developed anterior chamber angle and sets the stage for later glaucoma.

## Secondary Glaucomas Associated With Ocular Anomalies or Systemic Syndromes

Among the secondary glaucomas of childhood, the underlying pathophysiology is as varied as that in adults; age at presentation provides some clues as to the mechanism. Presentation at birth or shortly thereafter indicates a profound developmental abnormality of the anterior chamber angle. Presentation later in life usually suggests a different process. For example, patients with aniridia who present with obvious glaucoma at birth or early childhood have visibly abnormal anterior chamber angle structures; whereas when glaucoma presents later in life in patients with aniridia, the previously functional trabecular meshwork appears occluded by anterior migration and rotation of the rudimentary iris stump.<sup>24</sup> In patients with Sturge–Weber syndrome or its variants, presentation at birth is associated with a gonioscopic appearance of the anterior chamber angle that cannot be differentiated from that of primary congenital glaucoma. However, in those patients with glaucoma presenting later in life, elevated episcleral venous pressure is thought to be the cause.

Secondary angle closure may be caused by forward pressure from a process in the posterior segment, such as persistent fetal vasculature, retinopathy of prematurity, or retinoblastoma. Synechial angle closure, caused by chronic inflammation or neovascularization, is seen in a variety of settings. Primary angle closure that results from iris bombé is not generally seen in children except in cases of spherophakia, but when the pupil becomes secluded by an inflammatory or neovascular membrane or vitreous, iris bombé and subsequent angle closure may occur.

Secondary open-angle glaucomas also occur in young children. Both corticosteroid-induced and chronic uveitic glaucomas have been well described.<sup>25</sup> Open-angle glaucoma may develop long after blunt trauma to the eye has occurred<sup>26</sup> and may also follow the spontaneous bleeding of juvenile xanthogranuloma.<sup>27</sup>

## OCULAR MANIFESTATIONS

The typical infant with congenital glaucoma is usually referred initially to an ophthalmologist because of clinically apparent corneal edema (Fig. 10.21.1). Corneal edema may be subtle—especially in bilateral cases—or may be profound, with an enlarged corneal diameter and globe, breaks in Descemet's membrane (Haab's striae), and sometimes even acute hydrops. Often the commonly described triad of epiphora, blepharospasm, and photophobia has been present for some time but was dismissed until more alarming corneal edema became apparent. The epiphora of congenital glaucoma is often misattributed to congenital nasolacrimal duct obstruction, which is found in 5%–6% of unselected newborns.

The hallmark of all forms of glaucoma in infants and young children is ocular enlargement, which occurs because the immature and growing collagen that constitutes the cornea and sclera in the young eye responds to increased IOP by stretching. All parts of the globe may stretch in response to elevated IOP until 3 to 4 years of age, and glaucoma-related axial myopia may be seen until the early teen years. Measurement of axial length by ultrasound can be very useful in the diagnosis and monitoring of the pediatric glaucomas, particularly in unilateral or asymmetrical cases. With

**Fig. 10.21.1 Clinical Appearance of Primary Congenital Glaucoma.** This 8-month-old boy presented with an acute (3-day) history of corneal edema in the right eye. Note the enlarged corneas in both eyes and the epiphora. Intraocular pressure at examination under anesthetic was >35 mm Hg (>4.7 kPa) in the right eye. Trabeculotomy ab externo was carried out bilaterally.

**Fig. 10.21.2 Haab's Striae.** A retroillumination view of the right eye of the infant shown in Fig. 10.21.1 at 5 years of age. Haab's striae are seen just adjacent to the visual axis. The child is now 21 years old and has a best-corrected visual acuity of 20/50 (6/15) in the right eye, and 20/20 (6/6) in the left eye despite aggressive amblyopia treatment.

successful treatment, axial length often returns to a near-normal growth curve.<sup>28,29</sup>

Clinically, ocular enlargement is most easily discerned by an increase in corneal diameter. A variety of published series provide some guidelines as to normal measures of corneal diameter;<sup>30,31</sup> in general, the horizontal corneal diameter in the normal neonate is in the range of 10.0–10.5 mm and increases from 0.5 to 1.0 mm during the first year of life. In an infant in whom glaucoma is suspected, a horizontal corneal diameter >12 mm gives a high index of suspicion for the disease, as does asymmetry in corneal diameters of more than 1 mm.

As the cornea stretches and distends, Descemet's membrane and the overlying corneal endothelium may fracture and rip, which results in breaks presenting as profound corneal edema (see Fig. 10.21.1) and acute hydrops, in severe cases. As the endothelial cells migrate over the breaks and lay down new basement membrane, ridges develop along the separated edges of Descemet's membrane, resulting in the formation of the double striae first recognized by Haab<sup>32</sup> in 1899 (Fig. 10.21.2). In children above 2 years of age, corneal enlargement is usually not the predominant sign that glaucoma is present. In these children, decreased visual acuity or strabismus noted at the pediatrician's office or progressive unilateral myopia noted in an optometrist's office prompts the referral and the correct diagnosis.

The hallmark of all forms of glaucoma, and the principal cause of irreversible visual loss, is damage to the optic nerve. Early descriptions of infantile glaucoma stated that optic nerve cupping occurred late in the disease process.<sup>33</sup> It is now apparent not only that cupping may occur rapidly in infants but also that this cupping is reversible with surgical

**Fig. 10.21.3 Reversal of Optic Disc Cupping After Successful Treatment of Primary Congenital Glaucoma.** (A) Significant cupping in a 1-year-old child at the initial examination under anesthesia. (B) The same optic nerves 6 months after uncomplicated 360° trabeculotomy; note the dramatic reversal of optic disc cupping.

treatment and normalization of IOP.<sup>34</sup> Mochizuki and coworkers described a series of patients in whom optic disc cupping reversal was documented with digital photography; planimetry revealed that the scleral canal shrinks in size as the entire globe shrinks circumferentially.<sup>35</sup> Reversibility of optic nerve cupping is one of the hallmarks of successful treatment of glaucoma in infants and young children (Fig. 10.21.3). However, glaucomatous visual field defects and retinal nerve fiber layer thinning persist despite cupping reversal.<sup>36</sup> The short-term resilience of the infant optic nerve should be considered by the surgeon who contemplates incisional surgery based only on borderline anterior segment findings; if the optic nerve is normal, a repeat examination under anesthesia in a few weeks may spare the child an unnecessary intraocular procedure.

## DIAGNOSIS AND ANCILLARY TESTING

The diagnosis of glaucoma in infants is clinical. In most cases, particularly when the disease presents unilaterally or asymmetrically, the diagnosis is made in the office using a penlight (see Fig. 10.21.1). With some practice, IOP can be measured in the office in a conscious, swaddled infant using a Tono-Pen, handheld Goldmann (Perkins) tonometer, or Icare Rebound tonometer. Usually, the IOP in normal infants is in the range of 11–14 mm Hg (1.5–1.9 kPa) using these devices. The office measurement of an IOP greater than 20 mm Hg (2.7 kPa) in a calm, resting infant is suspicious for glaucoma when other signs and symptoms suggest the disease, as is an asymmetry of more than 5 mm Hg (6.7 kPa) in suspected unilateral or asymmetrical cases. Measurements of IOP undertaken while a child cries and resists efforts to hold the eye open are highly unreliable, since the Valsalva maneuver and lid squeezing can result in IOP readings

of 30–40 mm Hg (4.0–5.3 kPa), even in normal infants. In toddlers and older children, the Icare Rebound tonometer can be helpful in evaluating IOP and avoiding general anesthesia, but the device tends toward slightly higher values than Goldmann tonometry.<sup>37</sup> The recent recognition that central corneal thickness (CCT) can be an important confounder of accurate tonometry has led to investigations of CCT in children.<sup>38–40</sup> Variations in CCT may actually represent additional aspects of certain pediatric glaucoma syndromes such as aniridia.<sup>41</sup> The growing realization that tonometry is far less accurate in adults and children than previously appreciated underscores that the diagnosis of glaucoma in children should not be made solely on the basis of IOP measurement but on a constellation of findings. In addition, studies have shown that parents can learn to take accurate IOP measurements at home using Icare Rebound tonometry.<sup>42</sup>

Examination of the optic nerve is attempted whenever possible, as the presence of obvious glaucomatous cupping confirms the diagnosis. Shaffer and colleagues noted a cup-to-disc (C/D) ratio greater than 0.3 in 68% of 126 eyes affected by primary congenital glaucoma, whereas a C/D ratio greater than 0.3 was found in less than 2.6% of normal newborns.<sup>33</sup> Asymmetry in the C/D ratio between the two optic nerves—especially when the asymmetry corresponds with other findings—is strongly suggestive of glaucoma.<sup>43</sup> The optic nerve may also be monitored using optical coherence tomography (OCT) measurements of the retinal nerve fiber layer, and normative values in children have been found to be comparable to those in young adults.<sup>44</sup>

A Koeppel infant diagnostic lens that does not have a central depression employs a lid-retention flange to prevent the infant from squeezing out the contact lens. Once in place, good visualization of the disc is possible using a direct ophthalmoscope, even with a relatively small pupil. With dilation,

**Fig. 10.21.4 Gonioscopic Appearance of the Anterior Chamber Angle in Primary Congenital Glaucoma.** When viewed through a Koepple diagnostic lens, the iris is seen to insert anteriorly, and the peripheral iris is hypoplastic, unpigmented, and has a scalloped appearance. A sheen occurs over the angle structures (which is difficult to photograph) and gives the impression that a membrane coats the surface of the angle, but Barkan's membrane has not been identified histologically.

fundus photography to document the appearance of the optic nerve may be possible. With a Koepple diagnostic infant lens in place, gonioscopy may be performed, even in a conscious infant in the office. Simultaneous gonioscopy of both eyes may be carried out to compare the angle appearance in unilateral or asymmetrical cases. The diagnosis of glaucoma is not made using gonioscopic appearance alone but is based primarily on the other signs and symptoms of the disease. However, gonioscopy may help differentiate among the various forms of glaucoma and, most importantly, provide the surgeon with an idea of whether angle surgery (goniotomy or trabeculotomy) or fistulization surgery (trabeculectomy or drainage implant) should be the first intervention. The gonioscopic appearance of the anterior chamber angle in primary congenital glaucoma is characteristic (Fig. 10.21.4); the iris inserts anteriorly compared to the normal infant angle. The stroma of the peripheral iris is hypoplastic and unpigmented and has a scalloped appearance.

If the diagnosis of glaucoma is confirmed or strongly suspected based on the office examination, an examination under anesthesia (EUA) and definitive surgical treatment is pursued within a few days. Serial EUAs may be needed to monitor young children in whom only a limited exam can be performed in the clinic. However, the increased tolerability of Icare Rebound tonometry can reduce the number of EUAs needed for IOP monitoring.<sup>45</sup> Details of the EUA as well as goniotomy and trabeculotomy are provided in Chapter 10.27.

As noted previously, some forms of primary congenital glaucoma represent heritable disorders, as do many of the secondary or systemically associated glaucomas of childhood. All children who have glaucoma that presents at birth and in early childhood should be referred to a clinical geneticist familiar with ocular disease. In some cases, a subtle syndromic diagnosis may be made that has important implications for the parents' future child-bearing plans. Furthermore, the variable expressivity observed among *CYP1B1* mutations means that the siblings of affected children should be tested as well. If the same mutation is found in the clinically as-yet unaffected sibling, that child must be followed carefully. Due to advances in the molecular diagnosis of some forms of primary congenital glaucoma, it is now possible to offer prenatal screening for some families.<sup>46</sup>

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis of the various signs and symptoms of glaucoma in children is given in Box 10.21.1; this list is by no means exhaustive. Several acquired and genetic disorders may be mistaken as early childhood glaucoma.<sup>47</sup> Corneal cloudiness may have myriad causes. Corneal opacity that results from hereditary dystrophies is usually symmetrical, whereas corneal edema that arises from obstetric trauma is usually unilateral.

Corneal enlargement may result from megalocornea, which is frequently X-linked. In affected children, the anterior chamber angle, IOP,

### BOX 10.21.1 Differential Diagnosis of Ocular Signs and Symptoms in Congenital Glaucoma

#### Corneal Edema or Clouding

- Congenital hereditary endothelial dystrophy
- Mucopolysaccharidoses I, IS, II, III
- Cystinosis
- Sclerocornea
- Rubella keratitis
- Obstetric birth trauma ("forceps injury")
- Chemical injury

#### Epiphora and/or Red Eye

- Nasolacrimal duct obstruction
- Conjunctivitis (viral, chlamydial, bacterial)
- Corneal epithelial defect, abrasion

#### Photophobia

- Conjunctivitis
- Iritis
- Trauma (especially hyphema)

#### Corneal Enlargement

- Axial myopia
- Megalocornea (X-linked or sporadic)
- Microphthalmic fellow eye

and optic nerve are all normal, as are lens thickness and vitreous cavity axial length.<sup>48</sup> Some clinicians consider megalocornea to be a "forme fruste" of primary congenital glaucoma; such children should be followed carefully for later signs of glaucoma. An entirely normal eye may appear enlarged relative to a microphthalmic fellow eye, and in such cases familiarity with the age-appropriate corneal diameters and axial lengths prevents misdiagnosis.

Although the differential diagnosis of a red, tearing eye in a child is quite broad, the many potential infectious, malignant, or inflammatory causes rarely result in a diagnostic dilemma. Congenital nasolacrimal-duct obstruction occurs in 5%–6% of otherwise normal infants and coexists with congenital glaucoma with similar frequency. If epiphora persists after apparently successful treatment of glaucoma in an infant, the nasolacrimal system must be evaluated.

## CLASSIFICATION SCHEMES

In 2013, the Childhood Glaucoma Research Network (CGRN) and the World Glaucoma Association (WGA) arrived at a classification scheme for childhood glaucoma to assist clinicians and to form the basis of an international disease and surgical registry. An abbreviated version is provided in Box 10.21.2.

## PATHOLOGY

Descriptions of the pathology of the anterior chamber angle in primary congenital glaucoma are limited to a small number of specimens. This is because primary congenital glaucoma is rare, few of these infants die of unrelated causes, and incisional angle surgery does not involve the excision of a surgical specimen. Furthermore, eyes enucleated at an advanced stage for blindness and pain may not be representative of the earlier stage of the disease. Nonetheless, several general observations have been made.<sup>4</sup> The iris inserts anteriorly (see Fig. 10.21.4), but the angle is open; the trabecular meshwork appears open and is perforate; and Schlemm's canal usually is present and open. Although Barkan's membrane has not been identified conclusively, specific angle abnormalities have been described associated with mutations in *CYP1B1*.<sup>49</sup>

## TREATMENT

The preferred treatment of the congenital glaucomas is surgical (Table 10.21.1). Medical therapy alone is rarely effective for these conditions. Even topical prostaglandins, which can be administered once a day and may be safer (systemically) than those previously available, have limited efficacy in children,<sup>50,51</sup> and it remains unrealistic to expect more than short-term medication compliance in children who have a lifelong disease that may result in blindness.

Current techniques of surgery on the anterior chamber angle (goniotomy and trabeculotomy) enjoy a high rate of success in primary congenital glaucoma and can be used in selected cases of glaucoma following cataract surgery in which the anterior chamber angle is open.<sup>52</sup> In addition, alternative surgical approaches (trabeculectomy and drainage implant surgery) may be highly effective in the secondary congenital and childhood glaucomas.

The surgical management of all infants affected by glaucoma begins with a detailed EUA. There is an emerging body of literature that suggests excessive general anesthesia poses some risk to the developing infant brain.<sup>53</sup> Although the safety of general anesthesia in young children

is supported by more recent studies,<sup>54,55</sup> it is always best to avoid EUAs performed solely for diagnosis, thus committing the child to a second anesthetic for surgery. The ophthalmologist who undertakes the management of an infant or child who has glaucoma must approach the EUA with experience in pediatric gonioscopy and a flexible surgical plan. Surgical flexibility is particularly crucial in the case of the secondary congenital glaucomas, for which the surgeon must be prepared to alter the surgical plan depending on what is found intraoperatively. For example, in children with glaucoma following cataract surgery, the presence of a synechially closed anterior chamber angle is a contraindication to conventional angle surgery, as goniotomy or trabeculotomy can lead to iridodialysis or severe intraocular bleeding. In such cases, fistulizing surgery such as a trabeculectomy or drainage implant must be considered instead.

In primary congenital glaucoma, either goniotomy or trabeculotomy is the procedure of choice; these are associated with success rates of 90% or greater. Goniotomy requires the presence of a clear cornea for adequate observation of the anterior chamber angle; ab externo trabeculotomy may be performed in the presence of a hazy or opaque cornea. In a prospective trial in which bilaterally affected infants were treated with goniotomy in one eye and trabeculotomy in the other, Anderson found similar success rates for the two procedures.<sup>56</sup> The choice of which procedure to perform is left to the surgeon's discretion.

Circumferential (360°) trabeculotomy has become increasingly popular among pediatric glaucoma surgeons. These techniques involves the insertion of either a suture (e.g., blunted 6–0 polypropylene or nylon) or iTrack illuminated microcatheter device (Ellex Inc. USA, Minneapolis, MN) into the lumen of Schlemm's canal via an ab externo<sup>57</sup> or ab interno<sup>58</sup> approach followed by pulling the suture or catheter into the anterior chamber, transecting the trabecular meshwork, to create a circumferential trabeculotomy. The TRAB 360 device (Sight Sciences, Inc., Menlo Park, CA) is a single-use device that cannulates Schlemm's canal via an ab interno approach under direct gonioscopic visualization and can treat nearly 360° of the angle with two 180° passes. A comparison of 360° versus traditional (approximately 120° using the Harms trabeculotome) trabeculotomy showed significantly lower IOP in the group receiving 360° treatment.<sup>59</sup> However, 360° treatment may not be possible in certain cases due to incomplete Schlemm's canal development.

Trabeculectomy and trabeculectomy combined with trabeculotomy have been proposed as primary treatments for glaucoma in children.<sup>60</sup> However, a trabeculectomy in an infant eye is not without its own set of unique challenges. To raise a partial-thickness flap in a buphthalmic eye is particularly difficult, as is the postoperative adjustment of flap tension through lysis of flap sutures.<sup>61</sup> Hypotony, hyphema, or a flat chamber in an infant may easily result in profound amblyopia before the visual axis is cleared. Most proponents of filtration surgery in infants and young children advocate the intraoperative application of the potent antimetabolite mitomycin C, as there can be an exuberant scarring response, and postoperative injection of 5-fluorouracil is not an option without a general anesthetic. Filtration procedures augmented with antimetabolites result in the formation of thin acellular blebs that impart high susceptibility to late-onset bleb infection and endophthalmitis.<sup>62</sup> The use of fornix-based conjunctival flaps may reduce the risk of infection.<sup>63</sup> Encouraging results have been reported in young children with relatively few complications using this technique.<sup>64</sup>

### BOX 10.21.2 Abbreviated CGRN/WGA<sup>a</sup> Classification of Childhood Glaucoma

#### Definition of Childhood

- Based on national criteria: <18 years of age (USA); ≤16 years of age (UK, Europe)

#### Definition of Glaucoma—2 or More Required

- IOP >21 mm Hg (investigator discretion if EUA data alone)
- Optic disc cupping: a progressive increase in cup-to-disc ratio, cup-disc asymmetry of ≥0.2, or focal rim thinning
- Corneal findings: Haab's striae or diameter: ≥11 mm in newborn, >12 mm in child <1 year of age, >13 mm any age
- Progressive myopia or myopic shift coupled with an increase in ocular dimensions out of keeping with normal growth
- A reproducible visual field defect that is consistent with glaucomatous optic neuropathy with no other observable reason for the visual field defect.

#### Definition of Glaucoma Suspect—at Least 1 Required

- IOP >21 mm Hg on two separate occasions, or
- Suspicious optic disc appearance for glaucoma, i.e., increased cup-to-disc ratio for size of optic disc, or
- Suspicious visual field for glaucoma, or
- Increased corneal diameter or axial length in setting of normal IOP

#### Primary Childhood Glaucoma

- Primary congenital glaucoma (PCG)
- Juvenile open-angle glaucoma (JOAG)

#### Secondary Childhood Glaucoma

- Glaucoma associated with ocular anomalies
- Glaucoma associated with systemic disease or syndrome
- Glaucoma associated with acquired condition
- Glaucoma following congenital cataract surgery

EUA, Examination under anesthesia; IOP, intraocular pressure.

<sup>a</sup>The Childhood Glaucoma Research Network (CGRN)/World Glaucoma Association (WGA) international classification of childhood glaucoma is proposed to serve as a common classification scheme for an international internet-based disease registry as well as future publications and work on children with glaucoma. Further information may be found at <http://www.gl-foundation.org/resources-for-professionals> and <https://wga.one/wga/>.

TABLE 10.21.1 Surgical Management for Congenital Glaucoma

Con	<ul style="list-style-type: none"><li>• Conjunctival incision required</li><li>• Risks of blebitis, endophthalmitis, late bleb leak, exuberant scarring</li><li>• Avoid contact lens wear</li></ul>	<ul style="list-style-type: none"><li>• Conjunctival incision required</li><li>• Risks of strabismus, late endophthalmitis secondary to tube exposure</li></ul>	<ul style="list-style-type: none"><li>• Avoid in phakic patients</li><li>• May need re-treatment</li></ul>	<ul style="list-style-type: none"><li>• Greater risk of phthisis and chronic hypotony</li></ul>
CPC, Transscleral cyclophotocoagulation; ECP, endocyclophotocoagulation.				

CPC, Transscleral cyclophotocoagulation; ECP, endocyclophotocoagulation.

However, the prospect of a lifetime with a 1%–2% annual rate of infectious complications of filtration surgery must be considered when the surgical approach to these difficult cases is chosen.

Use of a glaucoma drainage implant is another alternative to consider in cases of congenital glaucoma for which conventional angle surgery has either failed or is unlikely to succeed.<sup>65</sup> This option is attractive particularly for patients in whom aphakia is managed by daily or extended-wear contact lenses, as the fistula into the eye is diverted posteriorly away from the edge of the contact lens and probably reduces the incidence of contact lens–facilitated endophthalmitis. Several series recently examined the results of the Baerveldt<sup>66–68</sup> and Ahmed<sup>69–71</sup> drainage implants in the pediatric population.<sup>72</sup>

In cases where conventional glaucoma surgery has failed to control IOP, cycloablative procedures such as cyclocryotherapy<sup>73</sup> or laser cyclophotocoagulation<sup>74,75</sup> may lower the IOP profoundly. In eyes in which the anterior segment is disrupted by previous surgery and the underlying disease, endoscopic cyclophotocoagulation may have significant advantage in that the ciliary body can be directly targeted.<sup>76</sup> Cyclodestructive procedures are painful and are always performed under general anesthesia in children. A long-acting retrobulbar block of bupivacaine 0.75% can be used to provide pain control for the first 12 hours after surgery.

Sympathetic ophthalmia has been described following cyclophotocoagulation,<sup>77</sup> and indeed one of the authors (JDB) follows a child in whom the previously normal fellow eye was nearly lost following cyclophotocoagulation of a blind hypertensive eye with Coats' disease.

## COURSE AND OUTCOME

Glaucoma in children may be recognized any time from birth to late childhood. The age of onset has prognostic implications, in that the child who presents with buphthalmos at birth is most likely to have more significant developmental angle anomalies and secondary damage to eye structures. It is these children—along with those who have more profound disorganization of the anterior segment (e.g., Peters' anomaly, sclerocornea, microcornea)—who require a surgical team approach that may involve penetrating keratoplasty, lensectomy, vitrectomy, and drainage implant. Despite aggressive treatment, most of these eyes achieve limited, if any, vision.

Fortunately, the child who has primary congenital glaucoma presenting a few months after birth (and before dense amblyopia or severe structural damage to the cornea or optic nerve has occurred) may expect a good outcome if the disease is detected and treated promptly. Although prognosis varies by subtype, long-term visual outcomes in retrospective studies of

pediatric glaucoma show that nearly 50% have visual acuities better than 20/70 or 20/100.<sup>78,79</sup> Furthermore, the results of various surgical series of goniotomy and trabeculotomy are reviewed in Chapter 10.27; in general, IOP is reduced in more than 90% of cases.

The surgeon who treats the child affected by glaucoma has many effective options for the management of a disease that uniformly resulted in blindness only 50 years ago. However, the goal of glaucoma treatment is more than the achievement of normal IOP—it is the achievement of normal visual function.<sup>78</sup> The child shown in Figs. 10.21.1 and 10.21.2 illustrates this clearly. Despite timely and successful surgical intervention in infancy and aggressive amblyopia treatment over the next 10 years, this patient has reduced vision (due to amblyopia) in one eye and enters adulthood with decreased binocularity. Nonetheless, at present this represents an excellent result. With earlier diagnosis and treatment through advancing knowledge of the molecular biology of this disorder, we are likely to see even better results in the coming decades.

# When to Treat Glaucoma

Tak Yee Tania Tai, Jody R. Piltz-Seymour

# 10.22

**Definition:** It is appropriate to treat glaucoma when glaucoma damage is detected or progressing or if there is a high degree of confidence that such damage will occur.

## Key Features

- Multiple factors must be considered when deciding whether or not the patient is to be treated for glaucoma.
- The most important factor is confirming that the patient has glaucoma.
- Assessment for glaucoma must include measurements of optic nerve structure and function.
  - Structure:
    - Evaluation of the optic nerve appearance, optic nerve, nerve fiber layer and macular ganglion cell, and inner plexiform layer thickness.
  - Function:
    - Visual field evaluation:
      - For example, HVF 24-2.
      - Perhaps 10-2, 30-2.
- High intraocular pressure alone does not define glaucoma, but it does considerably increase the risk of developing glaucomatous optic neuropathy.
- The decision as to when to treat must depend on the level of confidence of the clinician that the patient has glaucoma and that the patient's glaucomatous damage is likely to progress without intervention.

## INTRODUCTION

The decision to initiate therapy to lower intraocular pressure (IOP) is a serious one that has far-reaching consequences. Once started, therapy generally is continued for the rest of the patient's life. Patients may be subjected to untoward side effects, significant costs, and altered quality of life from the use of glaucoma medications. In addition, the public health impact of treatment is enormous; therapy is expensive and requires regular medical attention.

Determining when to start treatment is a complex decision-making process, which must be individualized for each patient. Any decision to initiate therapy must weigh the patient's risk factors for the development or progression of glaucoma against the risk of side effects and inconveniences of treatment. Although treatment efficacy is measured in terms of lowering IOP, preserving the optic nerve, and stabilizing the field of vision, clinicians must remember that the true goals of glaucoma therapy are preservation of functional vision and optimization of quality of life.

## ANALYSIS OF RISK FACTORS

The most important indications of the future risk for glaucomatous damage are the extent of damage already present and the current rate of progression of the disease.<sup>1,2</sup> The extent of damage may be assessed by evaluation of the status of the optic nerve, nerve fiber layer (NFL), and visual field. Stereoscopic evaluation of the optic discs is carried out to search for signs of glaucomatous damage, which include thinning of the neuroretinal rim (particularly at the superior and inferior poles), notching of the rim, disc hemorrhages, asymmetry between the appearance of the optic nerves, and peripapillary atrophy. Documentation with stereo disc photographs help in long-term monitoring. Evaluation of the NFL and optic disc with

imaging technologies, such as optical coherence tomography (OCT), can detect widespread generalized loss or focal arcuate defects in the NFL and macular ganglion cell loss before functional loss is present on automated perimetry. Visual fields are best evaluated by using threshold techniques of the central 24–30°. However, early glaucomatous visual field damage can also occur within the central 10° and can be missed by 24-2 or 30-2 visual field algorithms; thus 10-2 visual fields should also be considered in suspicious eyes to diagnose and monitor glaucoma.<sup>3</sup> Eyes affected by glaucoma exhibit characteristic nerve fiber bundle pattern defects with or without generalized depression (see Chapter 10.5). Not surprisingly, patients at greatest risk of blindness have visual field loss at the time of diagnosis.<sup>2</sup>

Documentation of progressive change of the optic disc, NFL, or visual field is the hallmark of the diagnosis of glaucoma but generally is not possible on initial patient encounters. The rate of progression can be determined only by serial examinations over time. Typically, standard threshold perimetry is performed 1–4 times per year. Stereoscopic nerve head evaluation is also performed at regular intervals, ideally with baseline and possibly interval stereophotographic documentation. Other psychophysical tests may be more sensitive in detecting early functional damage and in confirming progression. Short wavelength automated perimetry (SWAP) may be useful in detecting visual field loss in cases where a glaucomatous retinal NFL defect is strongly suspected, but standard automated perimetry does not detect any visual field abnormalities. SWAP has been reported to detect glaucomatous visual field loss in some patients as early as 5 years before standard achromatic perimetry.<sup>4</sup> Visual field loss in SWAP may also appear simultaneously with, or after, visual field loss in standard automated perimetry. SWAP is more time consuming, has greater variability and fluctuation, and is more affected by lenticular changes compared with standard automated perimetry. Short-duration transient visual evoked potentials (SD-tVEP) have been found to distinguish healthy individuals from patients with glaucoma with high sensitivity and specificity. In discriminating between healthy eyes and eyes with mild glaucoma (mean deviation on visual field of >–6.0), one study found that the sensitivity and specificity of SD-tVEP were 86.7% and 93.3%, respectively.<sup>5</sup>

Serial OCT evaluations of optic nerve, NFL, and ganglion cell complex play an important role in the assessment of the rate of progression over time.<sup>6,7</sup> As the imaging technology continues to evolve, and because it is difficult to compare data from older machines with those from newer machines, there is limited published data for measuring progression with OCT; however, spectral-domain OCT (SD-OCT) has been found to be more sensitive than time-domain OCT (TD-OCT) in detecting retinal NFL abnormalities and changes. SD-OCT glaucoma progression algorithms measure changes using event-based or trend-based analyses. Event-based analysis establishes a threshold for change from baseline and detects progression when a follow-up measurement crosses this threshold. Trend-based analysis establishes a slope of a measured parameter over time and is less susceptible to measurement variability compared with event-based analysis; however, this approach requires a large number of tests before the analysis can be considered reliable.<sup>8</sup> Detection of change is critical because it is believed that the risk of further injury accelerates as the disc injury progresses.

The Ocular Hypertension Treatment Study (OHTS) and the European Glaucoma Prevention Study (EGPS) were two randomized clinical trials designed to determine if lowering IOP reduced or delayed the onset of glaucoma damage.<sup>9</sup> Despite employing different protocols, both studies identified the same risk factors for the development of glaucoma: age, IOP, central corneal thickness (CCT), vertical cup-to-disc ratio (CDR), and the mean deviation of automated perimetry. Other risk factors that have been associated with the development of glaucoma include race, family history of glaucoma, myopia, ocular perfusion pressure, systemic hypertension, systemic hypotension, nocturnal hypotension, vasospasm (associated with

**Fig. 10.22.1** Prevalence of primary open-angle glaucoma in relation to screening intraocular pressure. The curves are smoothed using a running mean with window width of 7 mm Hg. For white American subjects,  $n = 5604$  eyes, and for black American subjects,  $n = 4464$  eyes. (Data from Tielsch JM, Sommer A, Katz J, et al. Racial variations in the prevalence of primary open-angle glaucoma. The Baltimore Eye Survey. *JAMA* 1991;266:369–74.)

cold extremities, migraine headaches, Raynaud's disease), and sleep apnea. Any decision to treat must also take into account psychosocial issues, such as the patient's overall health and predicted life expectancy, current systemic medications, risk of medication side effects, degree of patient understanding of the disease and treatments, level of compliance, and financial impact of treatment.

## RISK FACTORS

### Intraocular Pressure

IOP is the leading causal risk factor for glaucoma and, at present, the only risk factor for which modulation has been proven to be clinically efficacious. Both the incidence and prevalence of glaucoma increase with increasing IOP (Fig. 10.22.1). Compared with an IOP of 15 mm Hg (2.0 kPa) or lower, the relative risk of glaucomatous optic nerve damage increases 13-fold for an IOP of 22–29 mm Hg (2.9–3.9 kPa), and 40-fold for an IOP >30 mm Hg (>4.0 kPa).<sup>10</sup> However, because the population with lower IOP is vastly greater than that with higher IOP, the majority of patients with glaucoma will not have highly elevated IOP. Asymmetrical or unilateral glaucoma, including secondary glaucoma or angle-closure glaucoma, typically results in worse damage in the eye affected by the higher IOP. Numerous animal models of glaucoma have shown that chronically raised IOP induces glaucomatous optic neuropathy in both primate and nonprimate species.

Multicenter clinical trials have definitively proven that lowering IOP is beneficial in preventing ongoing glaucoma progression in eyes with manifest glaucoma damage. In the Advanced Glaucoma Intervention Study, when IOP was below 18 mm Hg on all visits over 6 years (average IOP of 12 mm Hg), almost no visual field progression ensued; for eyes with IOP <18 mm Hg on fewer than 50% of visits, visual field defect scores worsened by 0.63 units ( $P = 0.083$ ).<sup>11</sup> The Collaborative Normal-Tension Glaucoma Study demonstrated less visual field progression in patients with normal-tension glaucoma in whom treatment successfully reduced the IOP by 30% or more to an average of 11 mm Hg.<sup>12</sup>

The Early Manifest Glaucoma Trial randomized patients with early to moderate glaucomatous damage to treatment with laser trabeculoplasty and betaxolol or observation. Treatment reduced IOP, on average, by 25%, and average duration of follow-up was 6 years. Progression occurred later and less frequently in the treated group than in controls ( $P = 0.007$ ). In a multivariate analysis, progression risk was halved by treatment (hazard ratio [HR] = 0.50; 95% CI 0.35–0.71). The risk of progression decreased by about 10% with each millimeter of mercury that IOP was reduced from baseline to the first follow-up visit (HR = 0.90 per millimeter of mercury decrease; 95% confidence interval [CI] 0.86–0.94).<sup>13</sup>

Great variability occurs among individuals in the susceptibility of the optic nerve to damage from IOP. There is no IOP below which glaucoma never occurs or above which glaucoma always occurs. Of patients who suffer glaucoma, 50% have screening IOPs of <21 mm Hg (<2.8 kPa) and approximately one in six do not have IOP >21 mm Hg (>2.8 kPa) on repeated testing.<sup>8</sup> Although the relative risk of glaucoma is low when IOP is <20 mm Hg (<2.7 kPa), damage may still occur. Even when IOP remains

**Fig. 10.22.2** Kaplan-Meier plot of the cumulative probability of developing primary open-angle glaucoma (POAG) by randomization group. (Reproduced with permission from Kass MA, Heuer DK, Higginbotham EJ, et al. The Ocular Hypertension Treatment Study: a randomized trial determines that topical ocular hypotensive medication delays or prevents the onset of primary open-angle glaucoma. *Arch Ophthalmol* 2002;120:701–13.)

within the normal range, the risk of visual field loss is greater in the eye with the higher IOP.<sup>14</sup> Recent studies have suggested that variability of IOP, both diurnal and day-to-day fluctuations, rather than the absolute level of IOP may be paramount in causing progression of glaucoma.<sup>15</sup>

Ocular hypertension (OHT) is a common disorder that affects 3–6 million people in the United States. In a population over age 70 years, 10% of people suffer from OHT, whereas only 2% have primary open-angle glaucoma. The OHTS—a long-term, multicenter clinical trial sponsored by the National Eye Institute—was designed to determine whether medical reduction of IOP prevents or delays the onset of glaucomatous damage in subjects with OHT.<sup>16,17</sup> It also sought to determine the risk factors involved in the glaucomatous process. More than 1600 subjects were enrolled and followed up for more than 5 years.

Patients were randomized to medical treatment (using any of the topical medications approved by the U.S. Food and Drug Administration) or observation. Goal IOP for subjects in the treatment group was a 20% reduction of IOP and an IOP <24 mm Hg (<3.2 kPa). Patients were monitored by using Humphrey visual fields (program 30-2) and stereoscopic optic disc photographs. The 5-year risk of developing glaucomatous optic disc and/or visual field loss was significantly reduced in the treated group; 9.5% of patients in the observation group developed glaucoma compared with 4.4% of those in the medically treated group (Fig. 10.22.2).<sup>18,19</sup> A later study involving the OHTS cohort initiated glaucoma medications in participants who were initially in the observation group, after a median of 7.5 years of observation without treatment. At the end of 13 years, 16% of the initial treatment group developed primary open-angle glaucoma (POAG), whereas 22% of the later treated group developed POAG. The benefit of treatment was most significant among patients with the highest 5-year risk of developing POAG (>13%), as calculated using the OHTS risk calculator.<sup>19</sup> Thus, in patients at low risk for OHT who agree to regular follow-up, it may be reasonable to delay treatment until early glaucomatous damage is detected.<sup>19</sup>

### Optic Disc Characteristics

A larger CDR has been shown to be an independent risk factor for the development of glaucoma,<sup>18</sup> although it may also be an indicator of early glaucomatous damage (Fig. 10.22.3). Nonetheless, when a clinician examines a patient for the first time, there is no way to know whether this appearance represents a change from baseline or a stable finding. Although a large CDR may be a normal finding in larger optic nerves, both the OHTS and the EGPS found a strong association between a large CDR and the development of open-angle glaucoma.<sup>9</sup> The Confocal Scanning

Laser Ophthalmoscopy Ancillary Study after the OHTS found that several baseline topographic optic disc measurements, alone or when combined with baseline clinical and demographic factors, were significantly associated with the development of POAG among OHTS participants.<sup>7</sup> SD-OCT has also been shown to be useful in diagnosing preperimetric glaucoma and for detecting glaucomatous progression; OCT has supplanted scanning laser ophthalmoscopy as the preferred imaging modality for glaucoma detection and follow-up.<sup>8</sup> Another important optic disc finding is the presence of a disc hemorrhage, which was observed to result in a 3.7-fold increased risk in the multivariate analysis in the OHTS.<sup>20</sup> Only 16% of these disc hemorrhages were detected by both clinical examination and review of photographs, whereas 84% were detected only by review of photographs, underscoring the importance of disc photos.

### Central Corneal Thickness and Corneal Hysteresis

One of the most surprising findings of the OHTS was the impact of CCT on the development of glaucoma in the OHTS. Overall, participants in the OHTS had thicker corneas than the average population with an average corneal thickness of  $573.0 \pm 39.0$   $\mu\text{m}$ , and a quarter of the OHTS subjects had CCT  $>600$   $\mu\text{m}$ . Black subjects had thinner corneas than white subjects had ( $555.7 \pm 40.0$   $\mu\text{m}$  versus  $579.0 \pm 37.0$   $\mu\text{m}$ ;  $P < 0.0001$ ). The OHTS determined that a thinner CCT measurement was a strong, independent predictive factor for the development of POAG (see Fig. 10.22.3). Participants with a CCT  $<555$   $\mu\text{m}$  had three times the risk of developing POAG compared with patients with CCT  $>588$   $\mu\text{m}$ .<sup>21,22</sup> The risk of developing POAG doubled for every 40  $\mu\text{m}$  decrease in CCT from the overall mean of 573.3  $\mu\text{m}$  in the OHTS and EGPS pooled sample.<sup>9</sup> Other studies have confirmed that a thinner CCT is a risk factor for glaucoma outcomes, such as the presence of advanced glaucoma damage, SWAP visual field defects, and further visual field progression.<sup>21–23</sup>

**Fig. 10.22.3** Baseline risk factors predictive for the development of glaucoma in the Ocular Hypertension Treatment Study (multivariate proportional hazard models). Significant baseline predictive risk factors included central corneal thickness (CCT); cup-to-disc ratio (CDR); intraocular pressure (IOP), Humphrey visual field pattern standard deviation (PSD). (Data from Gordon MO, Beiser JA, Brandt JD, et al. The Ocular Hypertension Treatment Study: baseline factors that predict the onset of primary open-angle glaucoma. Arch Ophthalmol 2002;120:714–20.)

The explanation for the relationship between thinner corneas and glaucoma progression is unclear. It is not yet known whether an increased risk results from underestimation of IOP in patients with thin corneas or whether a thinner CCT is a surrogate for greater susceptibility of the optic nerve to damage.

Corneal hysteresis, the viscous dampening of the cornea which reflects its ability to absorb and dissipate energy, has been a subject of recent study interest. Corneal hysteresis may be lower in patients with glaucoma compared with patients with suspicious-appearing optic discs but normal visual fields or patients with ocular hypertension.<sup>24</sup>

### Age

The risk of having or developing primary open-angle glaucoma increases with increasing age. The prevalence of glaucoma increases from 0.2% in individuals 50–54 years of age to 2% of the population 70–74 years of age (Table 10.22.1).<sup>23</sup> The incidence rates for the development of glaucoma over a 9-year period were also found to increase with age; the Barbados Eye Studies demonstrated a rate of 2.2% in patients 40–49 years of age and 7.9% in those aged 70 years or older.<sup>25,26</sup> Similarly, the prevalence of glaucoma in Latinos  $\geq 80$  years of age was 16 times higher than that in Latinos 40–49 years old.<sup>27</sup> Older age was a statistically significant predictive factor for the development of POAG over a 5-year period in the OHTS<sup>18</sup> (see Fig. 10.22.3). This increased prevalence of glaucoma with increasing age may relate to the longer exposure to elevated IOP, the greater susceptibility of the optic nerves in older adults to sustain damage from elevated IOP, or other physiological factors that are affected by advancing age, such as autoregulation and ophthalmic circulation.

### Race and Ethnicity

The incidence and prevalence of glaucoma varies by race. The Baltimore Eye Survey showed that the prevalence of POAG is 4.3 times greater in black Americans than in other races and that black Americans are 4–8 times more likely to go blind as a result of glaucoma compared with white Americans. In this series, the prevalence of glaucoma was 1.2% among black Americans 40–49 years of age, and 11.3% in those 80+ years of age (see Table 10.22.1).<sup>28</sup> In the OHTS, blacks had a higher incidence of glaucoma compared with other study participants, with an average annual risk of progression to POAG in excess of 2%<sup>16</sup> (see Fig. 10.22.3). However, the OHTS model also suggests that race is not an independent risk factor after adjustment for CCT and CDR.<sup>18,28</sup>

The Barbados Eye Study found a similar prevalence of POAG in the African Caribbean inhabitants of Barbados as was found in black Americans in Baltimore—4.4% of African Caribbean adults versus 0.8% of white Caribbean adults.<sup>25,26</sup> Recent studies have demonstrated a similarly increased risk in Hispanic Americans of primarily Mexican ancestry. The Los Angeles Latino Eye Study estimated the prevalence of POAG to be 4.7% in this population.<sup>27</sup> The Rotterdam study based on the Caucasian population of The Netherlands showed a prevalence of POAG of approximately 1%, similar to the prevalence found in the Baltimore Eye Survey among white Americans.<sup>29</sup>

### Family History

Family history is a well-described risk factor for glaucoma. The Baltimore Eye Survey noted a 3.7-fold increased risk of POAG in individuals who had a sibling affected by POAG and a 2.2-fold increased risk if a parent was

**TABLE 10.22.1** Prevalence of Definite Primary Open-Angle Glaucoma by Age and Race

Family Group	History	Cases		Controls		Odds Ratio (95% CI) <sup>a</sup>	Age–Race Adjusted Odds Ratio (95% CI) <sup>a</sup>

<sup>a</sup>Adjusted rate is modified for nonresponse to definitive ophthalmological examination. Difference (Black American – White American) = 5.10 – 1.19 = 3.91% (95% confidence interval, range 3.45%–4.37%). Adapted with permission from Tielsch JM, Sommer A, Katz J, et al. Racial variations in the prevalence of primary open-angle glaucoma. The Baltimore Eye Survey. JAMA 1991;266:369–74.

affected (Table 10.22.2).<sup>30</sup> Distinguishing patients with a history of blinding glaucoma from those with a family history of ocular hypertension or mild glaucoma may help in risk assessment. Patients should be questioned as to whether the family member required surgery or had any significant visual loss from glaucoma.

PRINCIPLES OF INITIATION OF THERAPY

Prior to the initiation of therapy in any patient, it is important to establish a baseline for future comparisons. The IOP of most people who do not have glaucoma varies by <4 mm Hg (<0.5 kPa) over a 24-hour period. Patients with glaucoma have large diurnal variations of IOP, which may change by >10 mm Hg (>1.3 kPa). Many patients have a regular diurnal pattern, most typically with a high IOP upon awakening, but other patterns also occur.

If the IOP is not dangerously high on the initial visit, it may be useful to obtain another IOP measurement on a separate visit or obtain the patient’s diurnal IOP variation prior to starting therapy. It is also important to obtain baseline documentation of optic disc appearance and visual field performance. Discs can be drawn, but stereophotographs provide a more accurate record. NFL assessment with OCT has become an indispensable part of glaucoma assessment and should be performed early in the course of treatment to establish a baseline for future comparisons. Perimetry should be performed to establish a baseline; because there is a steep learning curve, automated fields are performed at least twice to obtain an accurate baseline if the patient is inexperienced at perimetry.

INITIATION OF THERAPY IN THE GLAUCOMA PATIENT

Most patients who have moderate-to-severe glaucoma are started on therapy to lower IOP. These patients have developed optic disc damage at their baseline, have untreated IOP, and are very likely to have continued progressive damage over time if the condition is left untreated. In most of these patients, the benefit of treatment far outweighs the risk of complications.

POAG is a bilateral disease, although it is often strikingly asymmetrical. If damage is present in one eye only, it is important to first rule out secondary causes of unilateral open-angle glaucoma, which most commonly include pseudo-exfoliation, traumatic angle recession, and corticosteroid-induced glaucoma. If secondary causes of glaucoma are excluded, the damage in one eye is predictive of damage in the other eye, and treatment often is considered in both eyes.

It is also important to look for signs of pigmentary glaucoma in evaluation of a glaucoma suspect. In some cases, IOP may be easier to control or normalize over time in cases of pigmentary glaucoma. In addition, older patients who may appear to be normal-tension glaucoma suspects, may, in fact, be in the regression phase of pigmentary glaucoma. The presence of a “pigment reversal sign,” with denser pigmentation of the superior trabecular meshwork compared with the inferior trabecular meshwork, may be helpful in making this diagnosis.<sup>31</sup>

INITIATION OF THERAPY IN THE GLAUCOMA SUSPECT

The decision to initiate therapy is much more controversial in the patient who is suspected of having glaucoma. It is particularly important for glaucoma suspects to be involved in the decision process. A person may be classified as a glaucoma suspect for many reasons. The most common glaucoma suspect has elevated IOP—those with ocular hypertension. Glaucoma suspects may also have other risk factors, such as thin CCT, strong family history, or suspicious optic discs or visual fields.

It is difficult to determine if a suspicious-appearing optic nerve is truly glaucomatous. Great overlap exists between normal and diseased optic nerves. The average optic disc has a CDR of 0.3–0.4, but a wide variation of normal occurs. The significance of the size of the cup depends on the size of the disc.<sup>32</sup> It is difficult to determine whether the large disc with a high CDR is pathological or physiological. Progressive disc changes may develop while visual field tests remain normal, and substantial axonal loss may develop before defects occur on perimetry.<sup>33</sup> Therefore, a normal visual field test does not rule out glaucoma. Evaluation of the NFL may be particularly important in these cases. OCT can help distinguish pathological optic nerves from normal or identify diminished NFL. Computerized images need to be interpreted carefully because results can be misinterpreted if scan quality or operator input is suboptimal; in cases of large, small, or tilted optic nerves; and in patients with high refractive errors. The normative databases for some of the OCT instruments are limited with regard to racial diversity, and all exclude high refractive errors. Software and hardware upgrades in imaging techniques continue to improve the discriminatory accuracy.

Initiating treatment should be considered in patients with more suspicious nerves, if NFL loss is detected, or if other significant risk factors for glaucoma exist. As discussed, in patients who have early glaucoma, treatment may be deferred, especially in those with limited life expectancy. However, treatment may be initiated at an earlier stage in subjects in whom it is difficult to detect change in the optic nerve status over time. This includes patients who have anomalous discs, disc drusen, high myopia, and tilted discs, as well as patients in whom an adequate fundus examination cannot be performed. Similarly, treatment may be begun at a lower threshold in patients who are unable to perform visual field testing or in patients who suffer nonglaucomatous causes of visual field loss.

The initiation of therapy is most controversial in patients who have elevated IOP and normal optic nerves and visual fields. As noted above, although the OHTS showed a significant reduction in the development of glaucoma with treatment, approximately 90% of patients in the observation group did not develop glaucoma during the first 5 years of the study.<sup>16</sup> Although deferring treatment increases the risk of developing glaucoma in those with ocular hypertension, subsequent initiation of treatment immediately lowers future risk. Delaying treatment in low-risk individuals only minimally increased the risk of developing POAG, whereas delaying treatment in high-risk individuals resulted in a greater increased risk.<sup>19</sup>

Risk calculators have been developed to help estimate the 5-year risk of developing glaucoma. Using data from the OHTS and the EGPS the calculators incorporate age, IOP, CCT, pattern standard deviation (Humphrey automated perimetry), and vertical CDR ratio in determining the risk of developing glaucoma in patients with ocular hypertension.<sup>9</sup> The model is available online at <http://ohts.wustl.edu/risk> or as an app on mobile devices. In an analysis of 13-year follow-up in the OHTS, treatment was more beneficial in patients whose baseline 5-year risk of developing POAG was higher.<sup>19</sup> For the patients in the highest third of baseline risk, the cumulative proportion of patients developing glaucoma was 0.40 in the original observation group and 0.28 in the original medication group; among patients in the lowest third of baseline risk, the proportion of patients developing glaucoma was very low and almost identical, at 0.08 in the original observation group and 0.07 in the original medication group.

Cost-utility analysis of the OHTS data have been developed that support the early treatment of those individuals with IOP ≥24 mm Hg and a 2% or greater annual risk of developing glaucoma.<sup>34,35</sup>

CONCLUSIONS

The decision of when to treat a patient to prevent glaucomatous damage cannot be simplified into a straightforward algorithm, although risk calculators can aid clinicians in treatment decisions. Only the physician, in concert with the individual patient, can weigh the risk of early measurable glaucoma loss, quality of life impact, and other social aspects of treatment in determining the optimal time to initiate therapy. Fortunately, a great

deal of active investigation has facilitated our decision-making process over the last decade, permitting treatment decisions based on sound data from large-scale, prospective, randomized clinical trials.

## Which Therapy to Use in Glaucoma

## 10.23

Assumpta Madu, Douglas J. Rhee

**Definition:** Long-term therapeutic intervention to preserve visual function while minimizing the unintended effects of glaucoma treatment.

### Key Feature

- The choice of therapy (alone or in combination) for patients with open-angle glaucoma includes medical treatment, laser treatment, and incisional glaucoma surgery.

## INTRODUCTION

The goal of glaucoma therapy is to maintain quality of life by preserving visual function while avoiding complications.<sup>1</sup> This can be achieved by maintaining intraocular pressure (IOP) in the target range, achieving stable optic nerve/retinal nerve fiber layer (RNFL), and stable visual field results. The optimal therapeutic intervention is determined on the basis of tolerable side effects, the patient's quality of life, and the patient's life expectancy. Although evidence-based medicine provides population-derived probabilities for treatment success and adverse events in general, each patient must be assessed individually before a treatment decision is made.

Although IOP appears to be the main risk factor for damage in glaucoma (hence the need for a specific target pressure in an individual eye),<sup>2</sup> other factors may be involved.<sup>3</sup>

IOP remains the most rigorously proven treatable risk/disease factor. All current modalities of treatment are designed to lower IOP to the point where deterioration of the disc or field ceases, thus preserving the patient's health-related quality of life, with a minimum of complications or side effects. Secondary benefits may also be gained, but the primary intent is to lower IOP. In the future, IOP-independent treatments may be added to the clinician's armamentarium. Once therapy is indicated, the initial target IOP reduction should be at least 25% of pretreatment level. The suggestion that an IOP of 21 mm Hg, 17 mm Hg, and 14 mm Hg or less prevents further glaucomatous damage was based on population statistics; however, some patients continue to develop progressive glaucomatous disease at IOP below this level, requiring adjustment of target IOP throughout the course of care. Establishing in advance the degree to which IOP must be lowered to preserve vision is only an estimate and should be individualized such that lowering IOP is intended to arrest the progression of visual loss.<sup>4,5</sup>

The choice of therapy for patients who have open-angle glaucoma consists of medication, laser trabeculoplasty (LTP), and incisional glaucoma surgery (or a combination of these), traditionally in that order. As more information emerges on the comparative outcomes of various therapies and surgical devices and techniques become safer and less invasive, the traditional paradigm is being refined. The selection of the most appropriate therapy must take into account factors that pertain to the individual patient and to each individual eye, such as age, severity of glaucoma, and other risk factors.

## HISTORICAL REVIEW

Topical medications to treat glaucoma were first used in the 1870s, with the introduction of physostigmine and pilocarpine. Subsequently, other drug categories have been added to the treatment armamentarium, including nonselective sympathomimetics in the 1920s (e.g., epinephrine, dipivefrin [later, the alpha-agonist apraclonidine in the early 1990s]), oral carbonic anhydrase inhibitors (e.g., acetazolamide) in the 1950s, and

beta-blockers (e.g., timolol and levobunolol) in the 1970s. Up until the late 1990s, beta-blockers were the medical therapy of choice in the majority of newly diagnosed cases of open-angle glaucoma. In the mid- to late 1990s, selective alpha-2-agonists (brimonidine), topical carbonic anhydrase inhibitors (CAIs: dorzolamide and brinzolamide), and prostaglandin analogues (PGAs: latanoprost, travoprost, bimatoprost, unoprostone) were introduced. Combination products are also available (beta-blocker-PGA, beta-blocker-CAI, beta-blocker-alpha<sub>2</sub>-agonist) but availability significantly varies from country to country. Since the late 1990s, PGAs have been considered the first-line agent for the majority of open-angle glaucomas.

Argon laser trabeculoplasty (ALT) was first described by Wise and Witter<sup>6</sup> in 1979. Initial short-term success was followed by less than satisfactory long-term control in many cases, with the result that this technique is not used as much as it was initially.<sup>7</sup> Selective laser trabeculoplasty (SLT) was first described by Latina in 1995.<sup>8</sup> A long-term study that compared 180° of ALT with 180° of SLT found both techniques to be equally successful.<sup>9</sup>

The first use of full-thickness filtering surgery, in the form of trabeculectomy, to shunt fluid from the anterior chamber into the subconjunctival space is credited to Cairns<sup>10</sup> in 1968. This procedure has been modified over the years to give better results and fewer complications. Recent modifications include the use of antimetabolites (e.g., 5-fluorouracil or mitomycin C) and the ExPress device (Alcon; Ft. Worth, TX).<sup>11,12</sup> There is a growing number of microinvasive glaucoma surgery or minimally invasive glaucoma surgery (MIGS) for the treatment of mild to moderate glaucoma. These ab interno procedures are adjunctive and do not preclude the future use of trabeculectomy or glaucoma drainage devices. The current mechanisms of IOP reduction includes increasing trabecular outflow (Trabectome, iStent, Hydrus, gonioscopy-assisted transluminal trabeculectomy, suprachoroidal shunts [CyPass micro stent]; reduction of aqueous production [endocyclophotocoagulation] and subconjunctival filtration [XEN gel stent]). Other incisional surgeries include canaloplasty (iScience, Menlo Park, CA), deep sclerectomy, and viscocanalostomy, which are nonpenetrating but technically challenging procedures that can achieve a moderate drop in IOP.

## TREATMENT MODALITIES

### Medical Treatment

Medical treatment is the most common initial intervention to lower IOP. Medications lower IOP by either decreasing aqueous secretion or increasing drainage. A range of topical and systemic antiglaucoma medications is available. Topical medication classes include miotics, beta-blockers, epinephrine derivatives, carbonic anhydrase inhibitors, alpha-agonists, and prostaglandin analogues. Prostaglandin analogues are the most frequently used initial medication to lower IOP. Medication choices are made based on several factors, such as cost, dosing schedules, extent of IOP-lowering effect desired, and side effects. Both ocular and systemic side effects may occur with medications (see Chapter 10.24).

The most common side effects of antiglaucoma drugs are neither life- nor sight-threatening. However, rare serious complications can include pulmonary compromise from beta-blockers, acidosis syndrome and aplastic anemia from carbonic anhydrase inhibitors, and retinal detachment associated with miotic therapy. Most patients are able to tolerate one or more of these medications without experiencing any side effects.

Patient-related factors, such as compliance, coincident systemic diseases, drug interactions, and side effects, can affect the success or failure of medical treatment. Inadequate compliance may be the most serious limiting factor in the nonsurgical therapy of glaucoma. Factors that influence compliance include complexity of the medical regimen, side effects

**Fig. 10.23.1 Inflammatory Changes in the Conjunctival Tissue.** A comparison of conjunctival biopsies from patients who underwent primary surgery with those from patients who received at least two topical medications for a minimum of 1 year before surgery showed a significantly greater increase in the number of macrophages, lymphocytes, mast cells, and fibroblasts in the conjunctiva and Tenon's capsule and a significantly greater decrease in the number of goblet cells in the medically treated group. Representative photomicrograph from the group of patients who received long-term eyedrop therapy. The substantia propria shows a round cell infiltrate of mainly lymphocytes. (From Sherwood M, Grierson I, Millar L, et al. Long-term morphological effects of antiglaucoma drugs on the conjunctiva and Tenon's capsule in glaucomatous patients. *Ophthalmology* 1989;96:327–35.)

of the medications, and patient understanding of the disease and its treatment.<sup>13,14</sup>

Polypharmacy is undesirable, and it is occasionally preferable to switch within class if the patient is near their target IOP rather than to add more drops. Although controversial, prior administration of topical antiglaucoma medications may influence the subsequent outcome of glaucoma filtering surgery, as a result of the active drug, the preservative, or both (Fig. 10.23.1).<sup>15</sup> Antiglaucoma medication use is associated with increased cataract formation.<sup>16–18</sup>

## Laser Trabeculoplasty

LTP induces biochemical changes in the trabecular meshwork to enhance aqueous outflow (see Chapter 10.25). LTP, especially SLT, is considered a first-line intervention to lower IOP in certain patients. The Glaucoma Laser Treatment (GLT) trial compared topical timolol with ALT as initial therapy and found that ALT has an advantage in terms of IOP (1.2 mm Hg lower) and preservation of visual field (0.6 dB higher) after 7 years.<sup>7</sup> The GLT trial had a confounding methodological issue in that eyes were randomized, rather than patients, so that the topical timolol administered in one eye could have had a contralateral effect.<sup>7</sup> Randomized controlled trials (RCTs) comparing SLT (360°) with a topical PGA as initial treatment showed no difference in IOP control at 1 year of follow-up.<sup>19,20</sup> LTP may also increase the risk of subsequent trabeculectomy failure,<sup>21–23</sup> but this is controversial.<sup>24,25</sup>

## Surgery

Surgical options in the management of glaucoma includes trabeculectomy, implantation of aqueous tube shunts, nonpenetrating glaucoma procedures, minimally invasive glaucoma surgery, and endocyclophotocoagulation, all of which can be done in conjunction with cataract extraction, when indicated. The most frequently performed filtering operation is the trabeculectomy (see Chapter 10.29), and it remains one of the most effective. However, complications, such as choroidal detachment or endophthalmitis, even years later, can occur. In nonpenetrating filtration

**Fig. 10.23.2 Mean Intraocular Pressures.** Medicine versus laser versus surgery. (Moorfields Primary Treatment Trial; Migdal C, Gregory W, Hitchings R. Long term functional outcome after early surgery compared with laser and medicine in open angle glaucoma. *Ophthalmology* 1994;101:1651–7.)

surgery (deep sclerectomy and canaloplasty), the advantages of not entering the anterior chamber must be balanced against a steep learning curve, the frequent need for adjunctive medications or laser goniopuncture, and the tendency to produce IOPs that are higher than those after trabeculectomy.<sup>26,27</sup> Additionally, procedures and devices designed to shunt fluid from the anterior chamber directly into Schlemm's canal (also called *canal procedures*)—ab interno trabeculectomy (e.g., Trabectome; Neomedix, Tustin, CA) and iStent (Glaukos, Laguna Hills, CA)—are available, but produce modest benefits.<sup>28,29</sup> After initial surgical intervention, nonvalved tube shunts had an advantage in maintaining IOP control compared with trabeculectomy for patients with uncontrolled IOP after previous incisional surgery after 3 years of follow-up.<sup>30</sup>

## Cyclodestructive Procedures

Destroying the ciliary body can lower IOP by decreasing aqueous production. Cyclocryopexy is no longer routinely performed because of the higher risk of complications compared with laser cyclodestructive procedures. External cyclophotocoagulation (CPC) using a diode laser is generally reserved for after all incisional procedures have failed. Endoscopically guided cyclophotocoagulation (ECP) offers the potential benefit of increased selectivity of ablation, allowing it to be performed earlier in the treatment algorithm and in conjunction with cataract extraction. However, the effectiveness of ECP is more limited.

## TREATMENT ALGORITHMS

Traditionally, the initial standard therapy for primary open-angle glaucoma (POAG) is medical, with LTP and surgery reserved for patients who fail medical therapy. Generally, the progression is to LTP, followed by trabeculectomy, then tube shunt surgery, followed by CPC. (Note: Some practitioners will use multiple attempts at trabeculectomy or tube shunts.) New technologies, patient-specific factors, and disease-specific factors may alter this traditional stepping regimen. Furthermore, a number of clinical studies have challenged this traditional approach to therapy, and therefore reappraisal is necessary. The outcomes of these trials will continue to modify the criteria by which therapy is chosen.

To date, available evidence from prospective RCTs indicates that LTP is an excellent option compared with a topical PGA.<sup>19,20</sup> The Advanced Glaucoma Intervention Study compared ALT versus trabeculectomy in patients who had failed initial medical treatment, and it was found that persons of African descent had less visual field decline with ALT followed by trabeculectomy, whereas persons of European descent did better with trabeculectomy followed by ALT.<sup>31</sup> Although several prospective, multicenter studies outside the United States have found trabeculectomy more advantageous compared with medical therapy<sup>15,21,32–34</sup> (Figs. 10.23.2 and 10.23.3), the U.S.-based Collaborative Initial Glaucoma Treatment Study found no statistical difference in the rates of glaucoma progression despite a lower IOP in the surgically treated group, except with eyes whose baseline mean deviation was >less than –10 dB, where the advantage was with trabeculectomy.<sup>35,36</sup>

In general, canal-based procedures have excellent safety profiles, but modest effectiveness at IOP lowering.<sup>28,29</sup> Nonpenetrating surgeries also have excellent safety profiles and IOP results more comparable with those of trabeculectomy.<sup>37,38</sup>

**Fig. 10.23.3 Time to Treatment Failure by Treatment Group.** Medicine versus laser versus surgery. (Moorfields Primary Treatment Trial; Migdal C, Gregory W, Hitchings R. Long term functional outcome after early surgery compared with laser and medicine in open angle glaucoma. *Ophthalmology* 1994;101:1651–7.)

### BOX 10.23.1 Guidelines for Therapy in the Individual Patient

- Assess risk factors
  - Stage of disease
  - Family history
  - Myopia
  - Microvascular disease
  - Other risk factors
- Estimate a target pressure
- Medical therapy
  - Achieves satisfactory intraocular pressure (IOP) control in many cases
  - If problems with inadequate IOP, side effects, or compliance, consider alternative therapy
- Laser trabeculoplasty
  - Can be considered for primary therapy as well as after failed trabeculectomy
  - Adult patients who cannot tolerate medical therapy
  - Patients who are controlled inadequately and cannot or will not undergo surgery
- Surgery
  - If low IOP required or target IOP not reached with other treatments
  - Borderline control with medicine or laser
  - Poor compliance
  - Failed therapy with medicine or laser
  - Consider earlier surgery where appropriate, not only as a last resort!

## CONCLUSIONS

Several conclusions can be drawn from the completed studies with regard to the current role of medicine, laser, and surgery in the management of POAG. The goal of treatment of glaucoma is to maintain the IOP in a

target range such that there will no longer be progressive loss of visual field function. This permits the patient to maintain their health-related quality of life throughout their lifetime.

Medical therapy still has a definite place in the management of POAG and results in satisfactory IOP control in a good percentage of cases. The wider choice of eyedrops makes it even more important to select the most appropriate therapy for the individual patient.

LTP appears to be effective for the short-term control of IOP, but there is concern about the long-term efficacy of this treatment and it requires further study.<sup>39</sup> LTP, SLT in particular, can be considered as a primary treatment, and especially so in patients with compliance problems. These patients require continual monitoring because IOP control may be lost suddenly, with a resultant acute rise in pressure.

Filtering surgery can give excellent IOP control, but consideration should be given to the risk of complications. Early surgery can be a useful option if the IOP is not controlled by medical therapy, if a low target pressure is required and cannot be achieved with medical therapy, or if compliance is a problem.<sup>40</sup> Guidelines for therapy in individual patients are given in [Box 10.23.1](#).

# Current Medical Management of Glaucoma

10.24

Ronald L. Gross, Brian D. McMillan

**Definition:** Medical management of glaucoma is performed using eyedrops, or less often systemic (oral or intravenous) medication for reduction of intraocular pressure.

## Key Features

Medications for treatment of glaucoma (currently approved by the U.S. Food and Drug Administration):

- Chronic treatment:
  - Prostaglandin analogues (increase outflow):
    - Latanoprost:
    - Latanoprostene bunod.
    - Bimatoprost.
    - Travoprost.
    - Tafluprost.
  - Beta-blockers (decrease inflow):
    - Nonselective:
      - Timolol.
      - Levobunolol.
      - Optipranolol.
      - Carteolol.
    - Selective:
      - Betaxolol.
  - Alpha-adrenergic agonists (decrease inflow):
    - Brimonidine.
    - Apraclonidine.
  - Carbonic anhydrase inhibitors (topical or oral) (decrease inflow):
    - Dorzolamide.
    - Brinzolamide.
    - Acetazolamide.
    - Methazolamide.
  - Miotics (increase outflow):
    - Pilocarpine.
    - Phospholine iodide.
  - Rho kinase inhibitors (increase outflow):
    - Netarsudil.
- Acute treatment:
  - Osmotics (oral or intravenous) (vitreous dehydration):
    - Glycerin.
    - Isosorbide.
    - Mannitol.
  - Carbonic anhydrase inhibitors (intravenous) (decrease inflow):
    - Acetazolamide.

## INTRODUCTION

The number of available agents for the medical treatment of glaucoma has expanded greatly. Years ago, the choice was limited to miotics, epinephrine, and oral carbonic anhydrase inhibitors. The introduction of topical beta-blockers in the 1970s represented a significant advance. Topical carbonic anhydrase inhibitors, alpha-adrenergic agonists, and prostaglandin (PG) analogues have also become available, which effectively lower intraocular pressure (IOP) and have side-effect profiles that appear to be advantageous in the majority of patients. Because of their superior efficacy and systemic safety, PG analogues have become the preferred choice for initial medical therapy.

Another aspect of efficacy is the use of generic agents. Unlike for oral agents, it is not necessary to prove bioequivalence or equal effectiveness when topical ophthalmic generics are introduced. Although these generic agents may be less expensive, the physician, patient, and policymakers must determine whether these savings are sufficient to justify their use. Unfortunately, few data are available to help in these decisions.

It is important to recognize that no single medication can be used in all patients in all circumstances. Each of the available drugs has unique advantages and disadvantages. It is necessary to individualize each patient's treatment regimen to maximize the benefits and limit the undesirable effects. It is vital to select the best agent for each particular patient's needs.

The first step in accomplishing this aim is to educate the patient about their glaucoma and their therapeutic choices. This allows the informed patient to participate in decision making about their care. Besides improving drug selection, better patient understanding of the disease and its treatment improves compliance with the medical regimen. Compliance in glaucoma patients is difficult to assess, but selection of an appropriate agent results in maximization of lowered IOP, ocular tolerability, and safety, which not only treats the glaucoma effectively but also minimizes the impact of treatment on the patient's quality of life.

Currently, the effectiveness of a medication in the treatment of glaucoma is measured by its ability to lower IOP. However, the impact of other factors (e.g., blood supply of the optic nerve, local mechanical factors that affect the optic nerve, neuroprotection of the optic nerve) on glaucomatous optic neuropathy has been recognized. Although the clinical importance of these factors is not yet understood, it is anticipated that improvement in the efficacy of glaucoma treatment may include these parameters.

Once the decision to begin medical treatment has been made, specific techniques may enhance the therapeutic index of any topical ophthalmic agent. First, patients are encouraged to perform nasolacrimal occlusion or gentle eyelid closure after the instillation of all topical ophthalmic drops. Such maneuvers decrease the systemic absorption of drugs and increase their intraocular levels, thus improving the therapeutic index.<sup>1</sup> In patients on multiple topical agents, these maneuvers also reinforce the need to allow sufficient time between the instillation of different agents to allow absorption of the first one before any dilution by instillation of a subsequent one.

Second, with the increased number of choices, it is important to determine that the drug is effective and well tolerated by utilizing appropriate follow-up to determine adequacy in reaching target IOP, percent IOP reduction, and possible side effects. Finally, it is important to instruct the patient on how and when to instill medications. Discussion of the preferred technique of instilling drops in the inferior cul-de-sac is vital. To confirm correct use, it is helpful to have the patient demonstrate the technique of drop instillation on a subsequent visit. Studies suggest that compliance is reduced when the frequency of administration is more than twice daily, which may be an important factor in the design of the patient's regimen. It is critical that the regimen be one that the patient can reasonably be expected to perform.

## DRUGS THAT DECREASE AQUEOUS PRODUCTION

### Beta-Blockers

Soon after their introduction, beta-blockers became the mainstay of medical glaucoma therapy. Over time, the importance of patient selection has become clear.

## Mechanism

Beta-blockers decrease aqueous humor production by the ciliary body and hence reduce IOP.<sup>2</sup> Evidence suggests that this occurs only during the day and not during sleep.<sup>3,4</sup> This may be important in patients who experience some of the systemic side effects (e.g., lower blood pressure and pulse rate) at night, with the potential for disease progression without other therapy to lower IOP.

## Efficacy

Beta-blockers are effective topical agents, with the mean peak IOP lowered by 25% and the mean trough lowered by 20% using nonselective agents.<sup>4,5</sup> In general, nonselective agents lower IOP equally effectively.<sup>5,6</sup> With betaxolol, a beta-1-selective agent, IOP reduction is slightly less.<sup>7</sup> None of the beta-blockers should be used more than twice daily. Certain nonselective agents, including timolol, may be used once daily (QD). QD instillation may be more convenient for the patient, which enhances compliance and reduces the amount of drug used. Furthermore, many agents are available in more than one concentration. Lower concentrations are preferred and are as effective in the majority of patients. Unfortunately, no studies have proven that lower concentrations have a lower incidence of side effects or produce less severe side effects.

## Side Effects

Contraindications to beta-blocker use include asthma, severe chronic obstructive pulmonary disease, bradycardia, second- or third-degree heart block, and congestive heart failure. Clinically, it is prudent not to use this class of drugs in any patient who has reactive airway disease (asthma), has a heart rate of less than 55 beats per minute, has or has had heart failure, has a history of present or past use of antidepressant medications, or has impotence. A positive history of cardiac problems or symptoms is usually present in patients who have greater than first-degree heart block.

Although cardiac and pulmonary side effects are the most obvious, in a large review, central nervous system problems were the most frequent,<sup>8</sup> ranging from hallucinations to depression to a general feeling of malaise. These side effects may be much more difficult to identify. In the majority of patients, if the drug used may be causing or exacerbating such problems, it is stopped to establish whether the symptoms improve. Older adults appear to be at the greatest risk for beta-blocker side effects. A conscious effort is required to identify susceptible patients (in line with the overall philosophy of individualization of therapy and specific assessment of drug effects). Other systemic side effects of topical beta-blockers, including alopecia, a dermatological problem, are rare.<sup>9</sup>

Locally, beta-blockers are well tolerated, although corneal hypesthesia and epithelial changes have been reported.<sup>10</sup> Additionally, some investigators believe that their use should be avoided in patients with diabetes because the symptoms of hypoglycemia may be masked and those of myasthenia gravis may be exacerbated.<sup>11,12</sup> Furthermore, it has been suggested that patients who are undergoing allergy tests or desensitization should not use beta-blockers of any kind, even topical agents because beta-blockade may make resuscitation more difficult should anaphylaxis occur. The use of beta-blockers in neonates is avoided because apnea may develop.<sup>13</sup> The implication that beta-blockers may have an undesirable effect on plasma lipids is less well understood. Systemic beta-blockers are known to result in undesirable changes in plasma lipid profiles. However, systemically, they are actually protective when the clinical outcomes of elevated plasma lipids (i.e., heart attack and stroke) are considered because of their positive effect on cardiovascular function. Topical timolol and, to a lesser extent, carteolol reduce high-density lipoproteins by 9% and 3%, respectively; however, no data indicate that this results in a higher risk of cardiovascular disease.<sup>14-16</sup> Although it is true that topical beta-blockers are effective and well tolerated by the majority of patients,<sup>17,18</sup> it is the clinician's obligation to identify patients who may benefit most from their use and those in whom their use should be avoided and other classes of agents should, instead, be used.

## Alpha-Adrenergic Agonists

The first specific alpha-agonist introduced was apraclonidine, a relatively selective alpha-adrenergic agonist derived from clonidine.<sup>19</sup> Brimonidine is the alpha-adrenergic agonist that is more commonly used in chronic therapy.

## Mechanism

Apraclonidine decreases aqueous production<sup>20</sup> but is also associated with an increase in outflow facility and a decrease in episcleral venous

pressure.<sup>21</sup> Brimonidine is 23 times more alpha-2 selective than apraclonidine and 12 times more selective than clonidine.<sup>22</sup> Its mechanism of action includes a reduction in aqueous formation as well as an increase in uveoscleral outflow.<sup>23</sup>

## Efficacy

The first clinical use of apraclonidine was to decrease IOP in the prevention of pressure spikes after anterior segment laser surgery. It was shown to be very effective for this purpose after argon laser trabeculoplasty,<sup>24,25</sup> argon laser iridectomy,<sup>25</sup> neodymium-doped:yttrium-aluminum-garnet (Nd:YAG) laser iridotomy,<sup>21</sup> Nd:YAG laser capsulectomy,<sup>24</sup> and even cataract surgery and trabeculectomy.<sup>26</sup> Additionally, it was used successfully in cases of acute angle-closure glaucoma<sup>27</sup> and as prophylaxis against high IOP spikes after cycloplegia.<sup>28</sup> Apraclonidine is rarely used in the chronic treatment of glaucoma.

Brimonidine 0.5% prevents the rise in postoperative IOP after laser trabeculoplasty. Spikes greater than 10 mm Hg occurred in 1%–2% of cases using brimonidine versus 23% using vehicle.<sup>29</sup> In a 12-month comparison of twice-daily brimonidine 0.2% versus timolol 0.5%, both were found to be equally effective at the 2-hour peak. No tachyphylaxis was seen with either drug over the 12 months of the study. At trough (12 hours), IOP reduction was 3.7–5.0 mm Hg with brimonidine, compared with 5.8–6.6 mm Hg with timolol. There was no difference between the groups in terms of optic disc and visual field, which were unchanged in 94% of patients.<sup>30,31</sup> Brimonidine is approved for use three times a day (TID) but is commonly used twice daily (BID) because at the morning trough, there is no difference in IOP between the two regimens.<sup>32</sup> Adherence rates are better in the BID group (72+/- 19%) compared with TID (62+/- 16%). However, dose frequency is higher in the TID group, 1.9 +/- 0.5 vs. 1.4 +/- 0.4 per day.<sup>33</sup> Lower concentrations of brimonidine (0.15% and 0.1%) have been introduced with Purite as the preservative (Alphagan P), demonstrating similar IOP-lowering efficacy to brimonidine 0.2%.<sup>34</sup>

## Side Effects

Chronic use of apraclonidine is limited by the risk for allergic reaction (Fig. 10.24.1), which may be severe. Previous studies using apraclonidine 1% reported a variable incidence of allergic reaction of up to 48%.<sup>35</sup> Systemically, this drug is well tolerated, with the primary systemic side effect being dry mouth. Brimonidine shows no effect on mean heart rate, mean blood pressure, or pulmonary function.<sup>30</sup> In the longer term (6- and 12-month studies of brimonidine compared with timolol), adverse effects included dry mouth in 30% of patients and fatigue/drowsiness in 15.8% (as a result of which 2.5% of patients left the study), compared with 13.6% with fatigue ( $P = 0.342$ ) in the timolol groups.<sup>30</sup>

Ocular effects included conjunctival blanching in 11%–17% (vehicle, 9%) of cases and burning/stinging in 24% (timolol, 41%). Within this class of agents, the allergy often limits the drug's clinical usefulness. The allergic response caused by brimonidine 0.2% is approximately 5% at 3 months and 12% at 12 months.<sup>30,31</sup> A different formulation of brimonidine has been introduced that reduces the concentration to 0.15% or 0.1% and replaces benzalkonium chloride with a proprietary Purite preservative. The most significant clinical improvement with the new formulation is a reduced incidence of allergic reactions by more than 50% (7.1% versus 17.1%).<sup>34</sup>

Fig. 10.24.1 Follicular conjunctival reaction to apraclonidine.

Use of the Purite preservative could be a great advantage to patients in whom benzalkonium chloride causes ocular surface disruption. This includes patients who are particularly sensitive to the preservative, as well as patients taking multiple drops in whom toxicity may be cumulative.

Brimonidine has been suggested to have potential neuroprotective effects on the optic nerve and retinal ganglion cells. Animal data supporting this claim are extensive. The results of a single trial in humans (Low-Pressure Glaucoma Treatment Study [LoGTS]) demonstrated significantly greater preservation of visual field after 4 years in patients with low-pressure glaucoma successfully treated with brimonidine 0.2% compared with timolol 0.5% despite similar and minimal IOP reduction in both groups.<sup>36,37</sup>

Brimonidine is generally contraindicated in children under 2 years old because of the risk of side effects, such as bradycardia, hypotension, hypothermia, hypotonia, lethargy, and apnea.<sup>38-40</sup>

## Carbonic Anhydrase Inhibitors

### Mechanism

Carbonic anhydrase is an enzyme that catalyzes the reaction of water (H<sub>2</sub>O) and carbon dioxide (CO<sub>2</sub>) in equilibrium with H<sup>+</sup> and HCO<sub>3</sub><sup>-</sup>. The net effect of the enzyme on aqueous production is to generate bicarbonate ions, which are transported actively across the ciliary epithelial membrane into the posterior chamber (sodium is the primary cation); an osmotic gradient is established.<sup>41</sup> Water passively follows because of the presence of the gradient, which results in aqueous production. Inhibition of this enzyme results in lower IOP because aqueous production is decreased approximately 50% or more<sup>42</sup>; aqueous outflow and episcleral venous pressure are affected little or not at all.

An important property of carbonic anhydrase is that it is necessary to inhibit nearly 100% of the enzyme. This requirement resulted in the extended time of development of a topical preparation that results in lower IOP because of decreased aqueous production, but systemic effects are minimized.

Dorzolamide 2%, a topical carbonic anhydrase inhibitor, is different in structure from the oral agents. It has increased aqueous solubility and has suitable lipid-water solubility for corneal penetration, which allows for effective topical application. Brinzolamide 1% was introduced as a suspension with a more physiological pH than dorzolamide solution. This resulted in a reduced occurrence of stinging with brinzolamide, but this medication is associated with transient blurring of vision after administration as a suspension.<sup>43</sup>

### Efficacy

Oral acetazolamide, 500 mg BID, as single agent produced an IOP reduction of 33.8 ± 7.1 % reduction.<sup>44</sup> In a 2% dorzolamide TID regimen, the peak effect was a 22% reduction of IOP, with a trough reduction of 18%, an effect that was statistically significant ( $P \leq 0.01$ ) compared with placebo.<sup>45</sup> The efficacy of brinzolamide 1% was shown to be essentially equivalent to that of dorzolamide 2% when used either two or three times daily as a single agent.<sup>46</sup> Topical carbonic anhydrase inhibitors are a reasonable choice for concomitant therapy or as monotherapy when other more effective agents cannot be used.

### Side Effects

#### Oral

Carbonic anhydrase inhibitors lower IOP very effectively; however, their use in the chronic treatment of glaucoma is limited by the frequency and severity of side effects. The most common is a constellation of symptoms that include malaise, fatigue, anorexia, and depression.<sup>47</sup> Gastrointestinal discomfort, which includes nausea, a metallic taste, and diarrhea, is also common. The more severe complications that limit the use of these agents are less common. Metabolic acidosis may occur in patients who have severe hepatic or renal disease. Sick cell crisis may be exacerbated by the acidosis as well, so patients at risk for sickle cell disease must be tested before the use of oral carbonic anhydrase inhibitors. Some investigators suggest that the acidosis lowers IOP further which may explain the general observation that acetazolamide lowers IOP more effectively than methazolamide. Morbidity is associated with the 11–15-fold increase in the incidence of renal calculi,<sup>48</sup> which most commonly occur within the first 6 months of treatment. Once renal stones occur in patients on these agents, the likelihood is high that they will occur again.

The greatest concern surrounding the use of oral carbonic anhydrase inhibitors is the potential mortality from blood dyscrasias. All blood components—red blood cells, white blood cells, and platelets—may be affected.

In 1989, 139 cases of adverse hematological effects possibly related to carbonic anhydrase inhibitors were reported, with some fatalities attributed to their use.<sup>49</sup> This usually occurs within the first 6 months and appears to be an idiosyncratic reaction that is neither dose dependent nor time dependent.<sup>50</sup> As a result, few investigators believe that periodic screening blood tests are justified. In fact, a strong case could be made that with the availability of topical carbonic anhydrase inhibitors, the use of oral agents should be limited to acute situations. In acute situations, when IOP must be lowered maximally, 500 mg of acetazolamide given orally as tablets (250 mg tablet × 2, not sustained release) has the most rapid onset of action. Often, oral administration is not possible because of nausea and vomiting, in which case the intravenous route is preferred; the peak effect by this route occurs in 10–15 minutes.<sup>51</sup>

### Topical

In controlled clinical trials, only 5% of patients discontinued the drug because of drug-related adverse events, the majority of which were ocular.<sup>52</sup> As part of the controlled clinical trials, plasma and urine were tested, but no evidence of any hematological or urinary disturbances, which included acid-base or electrolyte changes, was found.<sup>52</sup> The effects on blood pressure or heart rate were minimal. The only frequent systemic side effect was a bitter taste, reported in approximately 25% of patients.<sup>53</sup> Clinically, this effect can often be reduced if the importance of nasolacrimal occlusion or gentle eyelid closure for a few minutes after the instillation of all ophthalmic drops is emphasized.

With regard to adverse ocular events, approximately one third of patients treated with dorzolamide 2% experienced some level of ocular burn, sting, or discomfort. Superficial punctate keratitis was found in 12% of patients. This burning was less frequent with brinzolamide 1%.<sup>43,46</sup>

As with the oral agents, inhibition of carbonic anhydrase within corneal endothelial cells, which could result in a negative effect on the corneal endothelium, has not been found clinically thus far. The overall allergic rate was approximately 10%. In general, dorzolamide and brinzolamide are well tolerated.<sup>46</sup>

As to the potential for sulfonamide allergy, the portion of the sulfonamide molecule that is most responsible for the allergic response is not present in dorzolamide. A recent study suggests that patients with a self-reported sulfa allergy had similar rates of adverse reactions compared with patients with other non-sulfa allergies and had similar rates of adverse reactions to PG analogues.<sup>54</sup> However, caution must be used when sulfonamide allergy is a possible problem.

The use of dorzolamide in children was reviewed retrospectively in one study; no significant health problems were identified with acute or chronic use of this drug.<sup>55</sup>

## DRUGS THAT INCREASE AQUEOUS OUTFLOW

### Miotics

Miotic agents have long been an important class of drugs in the treatment of glaucoma. Their use has declined because of the availability of alternative agents with more desirable side-effect profiles.

### Mechanism

Miotics are parasympathomimetic agents whose action increases the contractile force of the longitudinal muscle of the ciliary body on its insertion into the scleral spur. This results in an increased facility of outflow of aqueous through the effects on the trabecular meshwork.<sup>56</sup> The miotics either mimic the effect of acetylcholine (e.g., pilocarpine) or prevent the breakdown of endogenous acetylcholine by inhibition of the pseudo-cholinesterase enzyme (e.g., physostigmine).

### Efficacy

Miotics were the earliest drugs used for glaucoma, and they lower IOP by 20%–30%. They are additive to beta-blockers, adrenergic agents, and carbonic anhydrase inhibitors.

### Side Effects

Although miotics lower IOP effectively, the clinical use of these drugs is often limited by their local ocular tolerance. From a systemic standpoint, they are quite safe. Cholinergic effects, such as increased gastrointestinal motility and increased salivation, are quite rare.<sup>57</sup>

The local undesirable effects associated with these drugs include pupillary miosis as a result of stimulation of the iris sphincter, burning on instillation of the drops, brow ache and headache after the initial use of

the drops, myopic shift of refractive error because of contraction of the circular muscle of the ciliary body with the resultant increase in power of the crystalline lens, and exacerbation of symptoms of crystalline lens opacity from the pupillary constriction. Such effects are often dose related. Pseudo-cholinesterase inhibitors are cataractogenic in adults and cause iris pigment epithelial cysts in children, although the latter effect may be prevented with concomitant use of topical phenylephrine. The use of miotics has rarely been associated with the development of retinal detachments and cicatricial pemphigoid.<sup>58</sup>

Pilocarpine gel was introduced to provide convenient daily dosing at bedtime, with the expectation that the majority of the undesirable effects would wear off by morning but the therapeutic effect would be maintained throughout the day.<sup>59</sup>

Patients whose eyes have undergone cataract surgery tend to better tolerate miotics because the miosis is less severe, no induced myopia occurs, and the patients tend to be older and suffer less brow ache and headache with use.

## Prostaglandin Analogues

PG analogues are the most recent class of drugs added to the armamentarium of glaucoma medications. Latanoprost initially and then bimatoprost, travoprost, and tafluprost have been approved for use in glaucoma or ocular hypertension. PGs are derived from arachidonic acid and display a wide range of biological functions. Recent changes in this class have included the availability of generic latanoprost, travoprost, and bimatoprost 0.03% with its potential issues and the introduction of new formulations, including a BAK-free travoprost (Travatan Z),<sup>60</sup> a reduced concentration of bimatoprost (Lumigan 0.01%) to decrease moderate to severe hyperemia,<sup>61</sup> and preservative-free tafluprost (Zioptan).<sup>62</sup>

### Mechanism

Animal studies have suggested that PGs reduce IOP by increasing uveoscleral outflow because no effect was found on fluorophotometrically measured aqueous flow or on tonographical outflow.<sup>63,64</sup> Further studies suggested that uveoscleral outflow increases because of relaxation of the ciliary body muscle and dilated spaces between ciliary muscle bundles, in addition to the altered metabolism of the extracellular matrix that surrounds the ciliary muscle cells.<sup>65</sup> Because uveoscleral outflow does not end in the episcleral venous circulation, it is possible to obtain an IOP that approaches episcleral venous pressure (9–11 mm Hg [1.2–1.5 kPa]), which may be very desirable, particularly in normal-tension glaucomas<sup>66</sup> (see Chapter 10.11). It appears that the effect on the ciliary body is mediated through modulation of tissue matrix metalloproteinases.<sup>67</sup>

### Efficacy

In multicenter trials that compared latanoprost 0.005% QD with timolol 0.5% BID for 6 months, latanoprost reduced IOP by 25%–34% and was statistically more effective than timolol.<sup>68</sup> The peak effect occurs approximately 12 hours after instillation. In addition, latanoprost reduced IOP in patients, day or night, and there was no suggestion of loss of effect during the 12 months of treatment. Travoprost 0.004% is a synthetic analogue of PGF<sub>2α</sub>, as is latanoprost. In many respects, travoprost and latanoprost are similar. Mechanistically, both bind the PGF receptor, travoprost appears to bind with higher affinity than latanoprost, and both lower IOP by increasing uveoscleral outflow. Both are administered QD. Their efficacy appears to be similar as well. In phase III studies involving 605 patients, travoprost 0.004% QD demonstrated about a 1.0–1.3 mm Hg greater reduction in IOP compared with timolol 0.5% BID.<sup>69</sup>

A 12-month study directly comparing travoprost 0.004% and latanoprost 0.005% showed little difference in mean IOP reduction (6.6–8.1 versus 6.2–8.1 mm Hg, respectively) and showed a statistical advantage favoring travoprost at the 16:00 hours' time point of the diurnal curve.<sup>70</sup> In comparisons of bimatoprost QD and timolol 0.5% BID, bimatoprost demonstrated statistical superiority in all measures of effectiveness in lowering IOP.<sup>71</sup> Various studies have compared the efficacy of these three agents. In the only trial comparing all three agents for 12 weeks, there was no statistically significant difference in IOP reduction among the three agents, although there were consistent differences in the magnitude of IOP reduction.<sup>72</sup> In a 6-month trial comparing latanoprost and bimatoprost, there was a statistically significant greater IOP reduction with bimatoprost than latanoprost at all time points.<sup>73</sup> Additionally, the rationale of switching among different agents in the class has been supported by a study that showed patients that are nonresponders to latanoprost have a high likelihood (13 of 15) of obtaining at least a 20% reduction in IOP when using bimatoprost.<sup>74</sup> Managed

care and limitation or changing of access to specific agents is common. Guidance of expectations when switches occur among these medications has shown very reasonable continuation rates. In a large-scale switch from latanoprost to bimatoprost involving over 43 000 patients, approximately 90% of the patients switched were still on bimatoprost 20 months later. Interestingly, over 90% of the patients started on bimatoprost continued with that therapy.<sup>75</sup>

Given the increasing recognition of the importance of angle-closure glaucoma worldwide, there are data showing that latanoprost was effective in lowering IOP in these patients and that the efficacy was not associated with the mean angle width or the amount of angle closure resulting from synechial closure.<sup>76</sup>

### Side Effects

Reported side effects in controlled trials of latanoprost 0.005% QD included conjunctival hyperemia (generally mild, 36%), burning and stinging (25%), blurred vision (17%), itching (15%), foreign body sensation (33%), tearing (6%), and eye pain (13%).

Latanoprost resulted in increased iris pigmentation in 11%–23% of patients<sup>68</sup> (Fig. 10.24.2). In most cases, the eyes in which the iris color changed had a characteristic concentric heterochromia before treatment, with greater pigmentation around the pupil than in the periphery. In patients who have pure blue, gray, green, or brown eyes, the risk of increased iris pigmentation is estimated to be 4%. In patients who have mixed blue and gray-brown irides, the estimated risk is 20% at 2 years, and for patients who have green-brown or yellow-brown irides, the estimated risk is 50% at 1 year. This increased pigmentation occurs slowly but may be noticeable at 3 months, with a 6.8%–11.6% increase in pigmentation seen at 6 months and a 15.5%–22.9% increase at 12 months; rarely, 18 months is required for the increased pigmentation to become manifest. Iris nevi do not appear to be affected. This change in pigmentation does not increase or decrease after cessation of latanoprost.<sup>77</sup> Animal data suggest that increased pigmentation may result from increased production of melanin within the iris melanocytes, rather than from cellular proliferation.<sup>78</sup>

PG analogue-related orbitopathy, which often includes posterior migration of the lash line, horizontal eyelid shortening, deepening of the superior sulci, periocular erythema, meibomian gland dysfunction, and canthal deformities, has been described.<sup>79</sup> Periocular pigmentation occurs in 1% of patients treated with latanoprost and 6% of those treated with bimatoprost.<sup>80</sup>

There is a theoretical risk that PG analogues may break down the blood–aqueous barrier potentially worsening or reactivating uveitis, cystoid macular edema (CME) and herpes infections.<sup>81</sup> Findings from small studies utilizing flair meters support a breakdown in the barrier and associated CME seen in some patients with pseudo-phakia or aphakia<sup>82</sup> but has not been found to affect the incidence, progression, or response to treatment of diabetic macular edema.<sup>83</sup> There was also no worsening of anterior uveitis or development of CME in patients with uveitis treated with PG analogues compared with untreated fellow eyes.<sup>84</sup> Case reports have described the reactivation of herpes simplex keratitis when PG analogues were prescribed<sup>85</sup>; however, there are no high level data to suggest that PG use is strictly contraindicated.<sup>81</sup> Caution is, therefore, advised when prescribing PG analogues to patients with prior uveitis, CME, or herpes keratitis but may be indicated in patients whose condition is not controlled with alternatives.

The side effects among PG analogues are similar, but with a greater occurrence of hyperemia with travoprost than latanoprost (49.5% versus 27.6%) and a slightly lower chance of increased iris pigmentation (2.8% versus 5.2%).<sup>70</sup>

Hyperemia was found to be significantly more common with bimatoprost 0.03% than with latanoprost. The hyperemia appears to be conjunctival injection that is unrelated to either an allergic follicular conjunctival response or actual tissue inflammation. Overall, hyperemia occurred in about 45% of patients using bimatoprost 0.03%; the severity of the hyperemia was trace to mild, with less than 4% of patients discontinuing bimatoprost because of tolerability issues in this clinical trial. The incidence of moderate to severe hyperemia was substantially less with the reduced concentration 0.01% compared with 0.03% bimatoprost. Clinically, in some patients, the hyperemia is slightly greater and may be associated with mild burning. This appears to be most severe when beginning the medication and usually improves. Ocular evaluation showed no increase in aqueous flare. Ocular effects identified included eyelash growth, rare increase in iris color, and conjunctival hyperemia. At 12 months increased iris pigmentation with bimatoprost, evaluated by the treating physicians using photographs of patients' eyes, was only 1.5%.<sup>71</sup>

**Fig. 10.24.2 Iris Color Changes After Latanoprost Treatment.** (A) Before treatment in a patient with a green-brown iris. (B) After 6 months of latanoprost treatment, the iris shows increased pigmentation.

The experience with PG analogues has reassured us that this change in iris color is primarily a cosmetic concern and is often not recognized by the patient. Although the change is irreversible, it is common to treat patients until iris pigmentation changes occur and to make a decision later whether to continue the drug, based on the efficacy and the patient's input.

### Systemic Safety

Latanoprost 0.005% has a plasma half-life of only 17 minutes. Therefore, with the very low concentration delivered, minimal systemic side effects would be anticipated. No effect was found on resting heart rate, blood pressure, or blood and urine laboratory values. The use of latanoprost in young patients has not been evaluated. Bimatoprost demonstrated no effect on

blood pressure, pulse, hematology, urinalysis, or any other parameter of systemic safety.

## FIXED COMBINATION MEDICATIONS

Many different fixed combinations of these medications are available worldwide. In general, fixed combinations provide additional convenience to the patient with a decreased preservative load. Common formulations include timolol/dorzolamide (Cosopt, preservative-free Cosopt), timolol/brimonidine (Combigan), and brinzolamide/brimonidine (Simbrinza). Data show that the fixed combinations are more effective than either component alone.<sup>86</sup> Unfortunately, because of the minimal further IOP reduction provided by the addition of timolol to the prostaglandin analogs, the fixed combination of any of these medications has not been approved by the U.S. Food and Drug Administration (FDA) for use in the United States.<sup>87,88</sup> However, they are available in many other areas of the world.

## DRUG DEVELOPMENT PIPELINE

There are several new classes of medications currently being tested in phase III clinical trials. These medications would be the first new class of medication, if approved, since the FDA approval of latanoprost in 1996.

There are seven clinical trials on Rho kinase inhibitors, including ripasudil, which relaxes contractile tone of cells within the trabecular meshwork. Netarsudil, a Rho kinase/norepinephrine transporter inhibitor, has been found to reduce IOP by increasing outflow facility through the expansion of the juxtacanalicular connective tissue and dilating the episcleral veins<sup>89</sup> and may promote retinal ganglion survival.<sup>90</sup>

Latanoprostene bunod, a nitric oxide donating PGF<sub>2α</sub> analogue, may have improved efficacy over latanoprost alone via nitric oxide mediated relaxation of the trabecular meshwork and Schlemm's canal.<sup>91</sup>

Trabodenasol, a selective adenosine A1 receptor agonist that is thought to increase trabecular meshwork outflow facility, is also in early clinical trials.<sup>92</sup>

These medications represent possible new first-line treatments or, more likely, second-line treatments in addition to or in combination with currently available PG analogues.

## THE MEDICAL ARMAMENTARIUM FOR GLAUCOMA TREATMENT

As more experience with any drug is gained, its place in the decision-making process becomes clearer. Historically, beta-blockers were the most common first-line agents used in the medical treatment of glaucoma. However, with increasing experience with newer agents, specifically the PG analogues that facilitate outflow, they have been recognized as being more efficacious in lowering IOP and systemically safer than beta-blockers. As a result, they are generally the first-line agents in glaucoma treatment. When these agents are not appropriate, we still have other excellent choices, including the beta-blockers, alpha-agonists, and topical carbonic anhydrase inhibitors. In general, these agents are well tolerated by most patients, with a low rate of discontinuation attributable to the drugs. We must maintain vigilance to identify patients who should not receive these drugs because of the potential for ocular, pulmonary, cardiovascular, or central nervous system side effects. The current spectrum of glaucoma drugs is summarized in Table 10.24.1.

Because about 50% of patients with glaucoma take more than one class of agent, the availability of fixed combinations and an understanding of the characteristics of these agents are necessary to make the best choices for our patients. Data have also shown that utilizing a fourth topical medication may not have a clinically significant impact on IOP control.<sup>93</sup> Therefore, when using medications to treat glaucoma, it is imperative that the individual needs of the particular patient be considered. It is important to include the patient in the decision-making process, through education about the disease as well as discussion of the specific positives and negatives of the treatment options. The best regimen for an individual patient can be selected and tried using correct instillation techniques. In this way, maximal compliance, which is often difficult to achieve and a limiting factor in effective medical therapy for glaucoma, may be obtained.

TABLE 10.24.1 Drugs Used to Manage Glaucoma

Drug	Example	Mechanism of Action	Efficacy	Side Effects
Beta-blockers nonselective	Timolol Levobunolol Carteolol Metipranolol	Decreased aqueous production (waking hours only)	+ + +	Pulmonary: bronchoconstriction Cardiovascular: bradycardia/heart block Exacerbation of CCF Depression Impotence Death
Adrenergic agents nonselective	Epinephrine Dipivefrin	Outflow enhancement	+ (+)	External eye: toxic reaction
Alpha-adrenergic agents	Apraclonidine	Decreased aqueous production	+ + (+)	External eye: allergic reaction
	Brimonidine	Also, uveoscleral outflow increase with brimonidine		Lethargy Dry mouth Allergic reaction
Miotics	Carbachol Pilocarpine Echothiophate	Increased conventional aqueous outflow	+ + +	Eye ache Headache Dim vision
Carbonic anhydrase inhibitors				
Systemic	Acetazolamide	Decreased aqueous production	+ + + +	Malaise Blood dyscrasia Kidney stones
	Methazolamide			Depression Weight loss
Topical	Dorzolamide Brimonidine		+ +	Metallic taste
				Eye irritation
Lipids (Prostaglandin analogues, prostamides, decosanoids)	Latanoprost Travoprost Bimatoprost Tafluprost	Enhanced aqueous outflow (conventional and unconventional)	+ + + +	Iris color change Hyperemia Periocular skin pigmentation Orbitopathy

# Laser Trabeculoplasty and Laser Peripheral Iridectomy

10.25

Karim F. Damji, Simrenjeet Sandhu

**Definition:** Laser trabeculoplasty involves treatment to the trabecular meshwork to enhance outflow of aqueous humor from the eye, and laser peripheral iridectomy involves treatment to create a full thickness hole within the peripheral iris to alleviate pupillary block.

Key Features

- Laser trabeculoplasty: laser treatment to the trabecular meshwork to enhance outflow of aqueous humor from the eye.
- Laser peripheral iridectomy: laser treatment to create a full thickness hole within the peripheral iris to alleviate pupillary block.

Associated Features: Laser Trabeculoplasty

- Typically performed with argon or a frequency-doubled neodymium:yttrium–aluminum–garnet (Nd:YAG) laser.
- Indicated for ocular hypertension, primary open-angle glaucoma, pseudo-exfoliation, and a few select open-angle glaucomas.
- Immediate pressure spike can occur.
- May lose its effect over the long term.

Associated Features: Laser Peripheral Iridectomy

- Typically done with Nd:YAG and/or argon laser.
- Alleviates pupillary block angle-closure mechanism.
- Hemorrhage, uveitis, lens damage can occur.

LASER TRABECULOPLASTY

Introduction and Historical Review

The notion of anterior chamber angle photocoagulation, using a xenon-arc light source, was introduced by Zweng and Flocks in 1961.<sup>1</sup> Laser treatment of the human trabecular meshwork by puncturing Schlemm’s canal was performed initially by Krasnov in 1973, but the lowering of intraocular pressure (IOP) that he described was short-lived.<sup>2</sup> Ticho and Zuberaman noted that argon laser treatment of the angle was successful in lowering IOP despite lack of permanent trabecular openings.<sup>3</sup> Contemporary use of argon laser trabeculoplasty (ALT) is based on a report demonstrating safety and efficacy in a group of patients with open-angle glaucoma in 1979 by Wise and Witter.<sup>4</sup> In 1998, Latina et al. utilized a frequency-doubled neodymium:yttrium–aluminum–garnet (Nd:YAG) nonthermal laser to lower IOP successfully in patients with open-angle glaucoma.<sup>5</sup> This laser appears to selectively target pigmented cells with little or no damage to the surrounding structures, and hence is referred to as selective laser trabeculoplasty (SLT).<sup>6</sup> ALT and SLT are equally safe and effective in lowering IOP in open-angle glaucoma.<sup>7</sup> The mechanisms of action of ALT and SLT remain to be completely elucidated. With ALT, there appears to be a mechanical effect (one or more of tightening of the trabecular meshwork, opening intervening spaces, or opening a collapsed Schlemm’s canal) and/or a biological response (cytokines are released which open the meshwork spaces and wall of Schlemm’s canal and signal trabecular cells and/or macrophages to clear material that has accumulated within the meshwork). With SLT, a cellular or biological mechanism is more likely because the laser does not appear to cause shrinkage of tissue in animal models.<sup>8</sup>

Preoperative Evaluation and Diagnostic Approach

The main indications for laser trabeculoplasty include the following:

- First-line option in early to moderate stage OAG with IOP less than 35 mm Hg.
- Glaucoma suspects or those with open-angle glaucoma who are intolerant to medications, have difficulty with cost of medications, or are poorly compliant.
- Primary open-angle glaucoma (POAG) (including exfoliation, pigmentary, normal-tension, corticosteroid-induced glaucomas) uncontrolled with one or more medications.<sup>9–12</sup>
- Patients who may benefit from reduction in medication.

Relative contraindications include:

- Uveitic and neovascular glaucomas.
- Congenital or juvenile glaucoma.
- Aphakic or traumatic glaucomas.
- Inadequate visualization of trabecular meshwork.

Predictors for ALT success are presented in Table 10.25.1. With optimal patient selection, after ALT, IOP typically drops to 25%–30% below the initial IOP at 1 year (the effect fades with time at an attrition rate of about 10% per year). SLT offers a safe and effective IOP-lowering alternative to ALT in patients with open-angle glaucoma.<sup>7,13</sup> (Table 10.25.2).

IOP-lowering with SLT depends on baseline IOP but seems independent of trabecular meshwork pigmentation. Caution needs to be exercised,

TABLE 10.25.1 Positive and Negative Predictors of Argon Laser Trabeculoplasty Success

	Negative Predictors	Positive Predictors
Age (years)	<40	>65
Trabecular meshwork pigmentation	Little or none	Moderate to marked
Corneal clarity	Poor	Clear
Disease entities	Uveitic glaucoma	Pigmentary glaucoma
	Angle closure	Pseudo-exfoliative glaucoma
	Juvenile glaucoma	Primary open-angle glaucoma
	Angle recession	Low-tension glaucoma
Lens status	Aphakic or anterior chamber intraocular pseudo-phakia	Phakic or posterior chamber intraocular pseudo-phakia
Contralateral eye	Little effect	Strong effect

TABLE 10.25.2 Selective Laser Trabeculoplasty (SLT) Versus Argon Laser Trabeculoplasty (ALT): A Prospective, Randomized Clinical Trial

	Mean Intraocular Pressure at Various Time Points to 1 Year		
	ALT (SD)	SLT (SD)	P Value
Baseline	23.48 (4.21) (n = 87)	23.84 (4.88) (n = 89)	0.60
3 months	19.75 (4.79) (n = 73)	18.89 (4.71) (n = 76)	0.31
6 months	18.42 (4.20) (n = 79)	17.83 (4.33) (n = 79)	0.40
12 months	17.88 (3.92) (n = 74)	17.97 (4.74) (n = 73)	0.90
Reproduced from Damji KF, Bovell AM, Hodge WG, et al. Selective laser trabeculoplasty vs. argon laser trabeculoplasty: results from a one-year randomized clinical trial. Br J Ophthalmol 2006;90:1490–4.			

however, in patients with heavy degrees of meshwork pigmentation, as these patients are at higher risk for a sustained (irreversible) IOP spike.<sup>14</sup>

Treatment with ALT or SLT at 360° appears to be more effective than at 180° or 90°, but there is a higher risk of postoperative IOP spike. Studies suggest that both ALT and SLT can be utilized as first-line therapy in patients with open-angle glaucoma. In the Glaucoma Laser Trial the authors concluded that initial ALT is at least as effective as initial treatment with topical medication.<sup>15</sup> For SLT, two studies suggested that the laser can be utilized as first-line therapy, although follow-up in both these studies was limited to 12 months.<sup>12,16</sup>

One study by Hong et al.<sup>17</sup> suggested that repeating SLT once may be effective, but not as effective as initial treatment; however, much more work needs to be done in this area.

## General Techniques

### Patient Preparation

If the angle is closed or narrow, a laser iridoplasty or a peripheral iridectomy is performed beforehand to deepen and allow better visualization of the angle; a laser iridoplasty can be performed simultaneously with ALT, but when a peripheral iridectomy is performed, ALT is best deferred for a few weeks because of possible anterior chamber debris. A drop of apraclonidine (0.5%) or brimonidine (0.15% or 0.2%) is instilled in the eye 30–60 minutes preoperatively to minimize IOP elevation after treatment.

### Lens Choice

A Ritch or, more commonly, a three-mirror Goldmann lens with antireflective coating is used. The lens does not invert the image but reverses the position, such that the 12 o'clock position of the mirror represents the 6 o'clock position at the angle, the 1 o'clock position of the mirror represents the 5 o'clock position at the angle, and so forth.

### Equipment Preparation

The trabecular meshwork may occasionally be variably pigmented, and a pigmented Schwalbe's line or a ciliary body band may be confused with the trabecular meshwork. In this case, the corneal wedge reflex can help to locate Schwalbe's line (Fig. 10.25.1).

A topical anesthetic is instilled immediately before the procedure. The gonioscope is applied by using methylcellulose as the coupling agent. The procedure begins with the gonioscope at the 12 o'clock position (to visualize the inferior angle which is the deepest part of the angle), and the lens is typically rotated clockwise. To ensure delivery of laser energy with maximal efficiency, the aiming beam is always kept in the center of the mirror, round and sharp, keeping the gonioscope perpendicular to the laser beam. The lens is rotated after several applications.

### Treatment Guidelines

The laser spots for ALT are placed at the junction of the pigmented and nonpigmented trabecular meshwork, with a gap of about the diameter of one to two laser spots between spots (Fig. 10.25.2A). The author currently

**Fig. 10.25.1 Corneal Wedge Reflex.** A thin slit beam that is about 30–40° off center will demonstrate the anterior and posterior corneal beams that converge on Schwalbe's line. This is demonstrated on the right-hand panel of the schematic.

TABLE 10.25.3 Protocols for Laser Treatments

	ALT	SLT	MLT	Peripheral Iridectomy			Argon Laser Iridoplasty
				Argon		Yttrium–Aluminum–Garnet (YAG)	
				Light Irides	Dark Irides		
Spot size (μm)	50	400	300	50	50	Fixed	200–500
Spot duration (seconds)	0.1	0.3 nanoseconds	0.3	0.2	0.02–0.05	Fixed (nanoseconds)	0.2–0.5
Power (mW)	200–800	0.4–1.2mJ	1000	1000	1000	3–8 mJ	200–400
Number of spots	50 per 180°	50 per 180°	50–60 per 180°	15–25	25–100	1–5 shots (each burst consists of 1–3 pluses)	4–6 per quadrant. Typically treat 360°

**Fig. 10.25.3** Selective laser trabeculoplasty (arrow) versus argon laser trabeculoplasty treatment (arrowhead). (Courtesy M. Berlin, MD.)

treats 180° of the inferior angle in one session (it is generally best to treat the same portion of the angle first to avoid future confusion on completion of the remaining 180°). See Table 10.25.3 for recommended treatment guidelines.

Settings should be adjusted according to the tissue reaction endpoint, which is minimal blanching (see Fig. 10.25.2B). If the burn is too anterior, the treatment is more likely to be ineffective; if it is too posterior, it is more likely to create inflammation and peripheral anterior synechiae.

The selective laser has a relatively large 400 μm fixed spot size, which ideally should be centered on the trabecular meshwork. The energy is adjusted from 0.8 mJ downward or upward, depending on tissue response.

For SLT occasional bubble creation is the endpoint. The number of shots applied is about 50 over 180°, with 180–360° treated initially (if treating 360° then 90–100 spots are applied). The spots are almost confluent and span the entire angle width because of the large spot size (Fig. 10.25.3). Pre- and postoperative care is similar to that of ALT.

### Follow-Up

The IOP is measured 1 hour after LTP. If it is elevated, additional IOP-lowering medication is administered and the IOP is rechecked 30–60 minutes later. Topical prednisolone acetate 1% four times daily is prescribed for 4–7 days, and as long as the one hour IOP was similar to or lower than baseline, the patient can be seen 4–6 weeks later. If there is concern about IOP or inflammation, the patient can be reviewed after 1 week. If anterior uveitis is present at 1 week, topical corticosteroids are continued. With SLT, it is possible to use a topical nonsteroidal anti-inflammatory agent four times a day for 4–7 days instead of prednisolone acetate.

### Re-treatment

If 180° of treatment worked reasonably well, then completing treatment of the angle (i.e., treating the remaining 180°) is worth considering if IOP rises with time. However, the chance of success with a re-treatment (i.e., energy applied when the same area was previously treated) of the angle using ALT is considerably less than with an initial procedure, and the overall effect seems to wane considerably with time. With SLT, retreatment may be effective, but further data are needed in this area.<sup>17</sup>

### Complications

The most common risk is an IOP spike in about 3%–5% of patients, but this may be limited effectively using apraclonidine or brimonidine.<sup>18</sup> Corneal burns, which occur rarely, typically heal within a few days. There

have been reports of some cases that developed corneal edema within 1–7 days after SLT. It is not yet understood what may predispose a patient to corneal changes as a result of this procedure, although routine use of topical anti-inflammatory drops may help avoid this complication.<sup>19,20</sup>

### Outcome

A period of at least 4–6 weeks after ALT is required before the final result can be evaluated. In two long-term studies, ALT maintained IOP control in 67%–80% of eyes for 1 year, in 35%–50% for 5 years, and in 5%–30% for 10 years (i.e., an attrition rate of 6%–10% per year).<sup>21,22</sup> With SLT, IOP-lowering occurs within 1–2 weeks but can continue for up to 4–6 months after treatment; attrition of effect also continues for 3–5 years with a similar rate as ALT.<sup>8,23,24</sup>

## LASER PERIPHERAL IRIDECTOMY

### Introduction and Historical Review

Von Graefe<sup>25</sup> introduced surgical iridectomy for glaucoma in 1857. In 1920, Curran recognized that iridectomy was effective for angle-closure but not for open-angle glaucoma.<sup>26</sup> In 1956, Meyer-Schwickerath<sup>27</sup> demonstrated that an iridectomy could be created without the need for an incision, using xenon arc photocoagulation. This method failed to gain popularity, however, because of frequent occurrence of lens and corneal opacities.

Argon laser iridectomy (via photocoagulation) and, more recently, Nd:YAG laser (via photodisruption) iridectomy have essentially replaced surgical iridectomy in the vast majority of cases.

### Preoperative Evaluation and Diagnostic Approach

Laser iridectomy is the established procedure of choice for angle-closure glaucoma associated with pupillary block, whether primary or secondary, or acute, intermittent, or chronic.

### Indications

Laser iridectomy is indicated for therapeutic, prophylactic, and diagnostic indications:

- Therapeutic:
  - Acute angle closure.
  - Chronic (creeping) angle closure as long as the entire angle is not closed with peripheral anterior synechiae.
  - Mixed mechanism glaucoma.
  - Phacomorphic with an element of pupillary block.
  - Iris bombé.
- Prophylactic:
  - Patients with 180° or more of iridotrabecular apposition (i.e., occludable angle).
  - Patients who have had silicone oil placed in the eye; an inferior iridectomy is necessary to prevent pupillary block (silicone oil is lighter than water and would float up and block a superior iridectomy).
- Diagnostic:
  - Laser iridectomy also aids in the diagnosis of aqueous misdirection (see Chapter 10.19) and plateau iris syndrome (in a nonpupillary block narrow angle).

### Contraindications

Laser iridectomy is contraindicated in patients who are unable to sit and cooperate at the slit lamp, who have a cloudy cornea precluding adequate

visualization of the iris, or who have a flat anterior chamber with complete iridocorneal touch.

In such cases, surgical iridectomy may be preferred. Iridectomy is also contraindicated in situations where 360° of peripheral anterior synechiae exist (including neovascular glaucoma).

## General Techniques

### Argon versus Nd:YAG Laser

Both lasers are effective for the creation of iridectomies. The argon laser requires uptake of light energy by melanin pigment, but the Nd:YAG laser does not, and works well on all iris colors. The author prefers the Nd:YAG in light- and medium-colored irides because it is quicker and is associated with fewer late closures than argon laser.<sup>28</sup> In dark irides, however, some prefer pretreatment with the argon laser.

The Nd:YAG laser does not coagulate tissue, and small hemorrhages occur more frequently with this modality. Therefore, in eyes that have prominent unavoidable vessels or in patients affected by a bleeding diathesis, combined treatment may be preferred, first with the argon laser (to ablate vessels in the area) and then with the Nd:YAG laser (to establish a patent peripheral iridectomy).

### Patient Preparation

A drop of pilocarpine 1% is instilled twice, 5 minutes apart; miosis helps to stretch and thin the iris. A drop of apraclonidine 0.5% or brimonidine 0.2% is used a few minutes preoperatively to prevent a postoperative IOP elevation.

### Lens Choice

Two special therapeutic contact lenses limit eye movements and blinking, concentrate the energy delivered, magnify the target site, and act as a heat sink to minimize the risk of superficial corneal epithelial burns. The Abraham lens has a 66D planoconvex button. The Wise lens has a 103D planoconvex button, which concentrates the laser energy more compared with the Abraham lens because it minimizes the spot and magnifies the target even more; however, because of the higher power of the Wise lens, it is more difficult to focus. The other advantage of the Abraham lens is that energy delivered to both cornea and retina is four times less than that delivered to these tissues by the Wise lens.

## Specific Techniques

The iridectomy is typically placed in the peripheral iris under the upper eyelid to avoid ghost images that may arise through the iris hole when the iridectomy is bisected by the eyelid margin and/or the tear meniscus.<sup>29</sup> However, another study suggested that cortical cataract, rather than location of the iridectomy, correlates with ghost images.<sup>30</sup> Some practitioners choose a superior location for the iridectomy (typically 11 o'clock or 1 o'clock), whereas others choose a horizontal location (typically temporally or slightly inferotemporally). If iris crypts are present, these represent thinner iris segments and, as such, are penetrated more easily.<sup>31</sup>

### Argon Laser

Long pulses (0.2 seconds) are used for light-colored irides (blue, hazel, light brown), and short pulses (0.02–0.05 seconds) are used for dark brown irides. See Table 10.25.3 for recommended treatment guidelines.

A single area is treated with superimposed applications until perforation is obtained—that is, when a pigment within aqueous moves forward (“smoke sign” or “waterfall sign”) or, preferably, when the lens capsule is visualized through the patent iridectomy. Transillumination of the iridectomy is not an adequate indication of patency.

### Nd:YAG Laser

The Q-switched mode is used, which allows treatment independent of pigmentation. Iris blood vessels are avoided. The iridectomy spot may be placed anywhere between the 11 o'clock and 1 o'clock positions because bubble formation is minimal, or it may be placed temporally at the 3 o'clock or 9 o'clock positions. In a thick iris, the red aiming beams may be separated slightly if the focus is advanced toward the iris stroma. This retrofocusing of the beam delivers the full energy from the optical breakdown, facilitating breakdown of the thick iris. On some lasers, a posterior focus can be set (typically 75–100  $\mu\text{m}$ ) so that it is not necessary to manually focus more posteriorly. The energy used is 3–8 mJ with 1–2 pulses per shot, and one or more applications as required for penetration (see Table 10.25.3).

## Combined Argon–Nd:YAG Technique

Both argon and Nd:YAG lasers can be used in sequential combination for dark brown irides or for patients who are on chronic anticoagulant therapy. First, the argon laser (short-pulse mode; e.g., 0.05 s, with 900–1000 mW and 50  $\mu\text{m}$  spot) is used to thin the iris to 75%–80% of its original thickness and to coagulate vessels in the area. Then, the Nd:YAG laser is used, with the beam focused at the center of the crater with one or more pulses at 3–6 mJ to complete the iridectomy.

### Second Iridectomy

One patent iridectomy is almost always sufficient to relieve pupillary block. In rare instances where the long-term patency of the opening is uncertain or in the presence of inflammatory (uveitic) pupillary block, a second iridectomy may be made at the same sitting.

## Complications

### Intraocular Pressure Spikes

Elevated IOP occurs in approximately one third of eyes after treatment with laser,<sup>31</sup> but the use of apraclonidine 0.5% or brimonidine 0.2% significantly decreases this risk, except in individuals who are already on chronic apraclonidine treatment.

### Laser-Induced Inflammation

Laser-treated eyes may suffer transient iritis because of breakdown of the aqueous–blood barrier. Occasionally, inflammation may be quite severe, and posterior synechiae may develop. Prednisolone drops four times daily for 4–7 days should be used postoperatively.

### Iridectomy Failure

An iridectomy may fail because the opening created is too small or because perforation is not achieved, with a residual iris pigmented layer present. Theoretically, functional failure can be avoided with a peripheral iridectomy diameter of at least 50  $\mu\text{m}$ ; an iridectomy with a diameter of 100–200  $\mu\text{m}$  is ideal.<sup>32</sup>

### Diplopia

Diplopia, or a “ghost image,” is an occasional complaint, especially when the peripheral iridectomy is placed in a location where the upper lid bisects the iridectomy or there is a cortical cataract present in the region. In the former situation, this may be related to a prism effect created by the tear meniscus or the upper eyelid. Tinted glasses or sunglasses often improve symptoms. Intolerable monocular diplopia may be resolved by placing a cosmetic contact lens, or corneal tattoo, which blocks the light from the peripheral iridectomy but not from the pupil.

### Bleeding

Post-laser hyphema is not uncommon after use of the Nd:YAG laser and is generally minimal and self-limiting. Brisk bleeding during treatment may be stopped by applying direct pressure to the cornea using the contact lens to tamponade the bleeding site temporarily.

### Lens Opacities

The lens rarely may be damaged directly from laser irradiation or indirectly because of deficient nourishment of the lens (aqueous takes a short cut through the iridectomy and therefore has reduced contact with the central lens capsule). Opacities that are directly laser-induced tend to remain focal in the area of the peripheral iridectomy, away from the visual axis.

### Corneal Injury

Focal laser damage to the epithelium, Descemet's membrane, or endothelium occurs frequently but is usually transient. A shallow anterior chamber, pre-existing corneal edema, or pathological conditions of the cornea (e.g., guttae) make corneal injury more likely.

### Other Complications

Post-laser malignant glaucoma, retinal burns, and lens-induced uveitis are extremely rare but reported complications.

## Outcome

The patient can resume full activity without restrictions as long as no hyphema is evident. Patients are seen at 1 hour and then at 4 weeks after the procedure. Corneal status, IOP, anterior chamber reaction, and patency of the iridectomy with direct visualization are assessed

at each visit. Gonioscopy is critical to determine whether the angle has deepened.

If the peripheral iridectomy remains patent after 4–6 weeks and is of reasonable size, the opening usually remains open unless an active inflammatory response (e.g., uveitis, neovascularization) is present.

## LASER IRIDOPLASTY

Laser iridoplasty consists of the placement of a circumferential ring of nonpenetrating contraction burns at the far iris periphery, just inside the limbus, to contract the stroma and widen the angle. Laser iridoplasty is performed by the application of evenly spaced (4–10 burns per quadrant), large (200–500  $\mu\text{m}$ ), long (0.2–0.5 seconds), and low-powered (200–400 mW) burns at the far iris periphery through a goniolens or the Abraham iridectomy lens (see [Table 10.25.3](#)).

Laser iridoplasty does not require a clear cornea for the placement of the spots because the energy is relatively defocused. Laser iridoplasty is indicated in cases of plateau iris syndrome, plateau iris configuration when the height of the plateau is deemed sufficient to cause angle closure with pupillary dilation, pre-laser trabeculoplasty narrow angle (to increase visibility of the angle anatomy), and angle closure that is unresponsive to medical treatment and for which peripheral iridectomy cannot be performed because of corneal clouding.

## MICROPULSE LASER TRABECULOPLASTY

Micropulse later trabeculoplasty uses repetitive microsecond pulses with frequent periodic pauses, thereby decreasing coagulative damage by allowing intermittent cooling periods from consistent thermal energy.<sup>31,33</sup> The biochemical theory proposes cytokine release, resulting in increased outflow.<sup>32</sup> Studies have revealed a significant IOP reduction in patients with uncontrolled open-angle glaucoma with minimal complications.<sup>34,35</sup> Newer laser treatment modalities, such as titanium sapphire laser trabeculoplasty, have also shown early promising IOP reductions with minimal complications.<sup>36</sup> However, more studies are needed to determine treatment safety and efficacy. See [Table 10.25.3](#) for recommended treatment guidelines.

# Cyclodestructive Procedures in Glaucoma

10.26

*Katherine A. Fallano, Ian P. Conner, Robert J. Noecker, Joel S. Schuman*

**Definition:** Surgical and laser procedures that ablate the ciliary body to lower intraocular pressure for treatment of glaucoma.

## Key Features

- Use of a diode laser to destroy ciliary body tissue.
- Transscleral cyclophotocoagulation.
- Endoscopic cyclophotocoagulation.
- Transscleral micropulse diode laser.

## Associated Features

- Neovascular glaucoma.
- Endstage glaucoma.
- Combined cataract surgery and endoscopic cyclophotocoagulation.
- Hypotony.
- Chronic inflammation.
- Phthisis.

## INTRODUCTION

Cyclodestructive procedures reduce intraocular pressure (IOP) by decreasing aqueous production through destruction of the nonpigmented ciliary epithelium responsible for producing aqueous. Historically, destruction of the ciliary body has been difficult to titrate and can cause significant damage to adjacent structures and permanent alteration of the blood-aqueous barrier. Therefore, these procedures were reserved for eyes that had glaucoma refractory to medical, laser, and surgical treatment. Newer technologies have resulted in improved selective targeting of the ciliary epithelium with a reduction in the associated side effects of phthisis bulbi, visual loss, and unpredictable IOP reduction. Micropulse application of the diode laser has recently emerged as an additional treatment option that may further mitigate these risks.

## HISTORICAL REVIEW

Selective destruction of the ciliary body with nonpenetrating diathermy was described by Weve in 1933, and penetrating diathermy was described by Vogt in 1936. Destruction of the ciliary body by freezing or cryotherapy was introduced in 1950 by Biette and found to be less destructive and more predictable compared with cyclodiathermy.<sup>1</sup> However, the IOP reduction was still inconsistent, and the complication rate was relatively high.

Cyclophotocoagulation was made possible with the introduction of the xenon arc photocoagulation in 1961 and the ruby laser in 1971. The transpupillary route of laser delivery was hampered by limited visualization of the ciliary processes. Despite the absence of visualization, the transscleral route became the preferred method of cycloablation in cases of refractory glaucoma. In 1981, Fankhauser described a longer pulse duration thermal ablation using a neodymium:yttrium-aluminum-garnet (Nd:YAG 1064 nm) laser system to perform transscleral cyclophotocoagulation (TCP). The availability of the instrument facilitated wide clinical use,<sup>2</sup> but the introduction of a solid-state diode (810 nm) laser equipped with a disposable probe increased economy and accessibility.<sup>3-9</sup> More recently, endoscopic cyclophotocoagulation (ECP) with the use of a diode laser equipped with an endoscope has allowed direct visualization and targeting of the ciliary epithelium.

## PREOPERATIVE EVALUATION AND DIAGNOSTIC APPROACH

Cyclodestructive procedures are usually reserved for eyes with poor visual potential (<20/400), eyes in which incisional procedures have failed, eyes in which filtering surgery has a high failure rate (e.g., extensive conjunctival scarring, neovascular glaucoma, aphakic and pseudo-phakic glaucoma, and glaucoma associated with silicone oil), and eyes of patients who have a medical contraindication to filtration surgery.<sup>10</sup>

The risks of cyclodestructive surgery include inflammation, pain, chronic hypotony, macular edema, vitreous hemorrhage, and phthisis. Because of these risks, proper technique and patient selection are critical to achieving the desired therapeutic result. Improved treatment parameters in TCP has led to a reduction in side effects and a willingness to use the procedure in eyes with better vision. In ECP, cyclophotocoagulation is guided by visual endpoints that limit overtreatment and damage to non-targeted tissue. Indeed, the role of ECP has expanded and is now used in nonrefractory glaucoma, in pediatric glaucomas, in combination with cataract extraction, and in cases where glaucoma filtering surgery carries higher risks of complications and failure.

## MECHANISM OF ACTION

Cyclocryotherapy nonselectively damages the epithelial, vascular, and stromal components of the ciliary body. TCP lowers IOP by destroying ciliary epithelium and the associated vasculature, leading to decreased aqueous humor production. The semiconductor diode laser with a wavelength of 810 nm has lower scleral transmission compared with the previously used Nd:YAG laser (1064 nm) but greater absorption by melanin. This allows the use of 50% less energy compared to the continuous wave Nd:YAG laser to achieve the same therapeutic effect.

TCP laser energy is more effectively absorbed by pigmented tissue in the ciliary body compared with cryotherapy, which is diffusely absorbed by all structures. Contact methods of TCP produce less scatter and thus require less energy than the noncontact methods.<sup>2</sup> As a result, the contact method of treatment is preferred and has been traditionally indicated in advanced glaucoma, in which the IOP is inadequately controlled despite maximal treatment.

Histologically, both diode and Nd:YAG lasers used for TCP produce fragmentation and detachment of the epithelium of the ciliary processes with simultaneous destruction of the ciliary body vasculature.<sup>11</sup> At least three mechanisms are thought to be important in lowering IOP: (1) inflammation, which is prominent in the first week or so after treatment; (2) decreased aqueous production through ablation of the pars plicata, through either a direct or indirect effect on the vasculature; and (3) increased uveoscleral outflow resulting from laser delivery to the region of the pars plana.<sup>9</sup>

ECP diode laser treatment appears to limit coagulative necrosis to the ciliary epithelium and stroma of the ciliary processes, thus acting largely to decrease aqueous production at the level of the ciliary body epithelium.

## ALTERNATIVES TO A CYCLODESTRUCTIVE PROCEDURE

The alternatives to a cyclodestructive procedure include fistulizing surgery by trabeculectomy or drainage implantation. The TCP procedure is advantageous because it is quick, is external, and can be performed in the office.

It is generally reserved for eyes with poor visual potential because of the risk of chronic inflammation and decreased visual acuity. ECP must be performed in the operating room and does not effect a rapid drop in IOP but is less likely to result in pain, inflammation, and overtreatment compared with TCP.

## ANESTHESIA

The ciliary processes are highly innervated and painful to treat without adequate anesthesia. Transscleral procedures require local (retrobulbar or peribulbar) anesthesia and can often be performed in an office setting. ECP requires local (topical with intracameral lidocaine, retrobulbar/peribulbar block) or general anesthesia and is performed in an outpatient surgical or hospital setting.<sup>4</sup> Most glaucoma medications are continued before and after cyclodestructive procedures and are discontinued only if an adequate IOP lowering is achieved. Epinephrine drugs, miotics, and prostaglandin analogues should be used with caution postoperatively because of the risk of increased inflammation and its associated complications.

## SPECIFIC TECHNIQUES

### Cyclocryotherapy

Cyclocryotherapy has fallen out of favor because of its poor risk/benefit profile and inadequately controlled application. (The interested reader is referred to the third edition of this text.)

### Transscleral Cyclophotocoagulation

#### Noncontact and Contact Nd:YAG Laser

#### Cyclophotocoagulation

Nd:YAG laser cyclophotocoagulation has been largely supplanted by contact diode laser cyclophotocoagulation and has also fallen out of mainstream use. (The interested reader is referred to the third edition of this text.)

#### Semiconductor Diode Laser Transscleral Cyclophotocoagulation

Diode laser TCP is the most widely used method of ciliary ablation with reported success rates ranging from 40%–80%. The technique used for the semiconductor diode laser (wavelength 810 nm) is similar to that used for the contact Nd:YAG laser (Table 10.26.1). The anterior edge of the probe approximates the surgical limbus so that the laser beam is directed 1.2 mm posteriorly toward the ciliary processes (Figs. 10.26.1 and 10.26.2). Starting settings are 1500–2500 mW for 1.5–3 seconds and a total of 18–24 spots (Fig. 10.26.3). The 3 o'clock and 9 o'clock positions are spared. The results are similar to those achieved using Nd:YAG TCP<sup>3,4,10</sup> despite using lower energy (55% of that used with the Nd:YAG laser). In addition, because semiconductor diode lasers have a solid-state construction, they have the advantages of portability, durability, and smaller size compared with the Nd:YAG laser<sup>3,4</sup> (see Fig. 10.26.3).

#### Micropulse Diode Cyclophotocoagulation

The micropulse diode is a newer mode of delivering laser energy to the ciliary body. TCP delivers continuous energy to the ciliary body, whereas the micropulse delivers short bursts alternating with rest intervals, with

a typical on–off duty cycle of 31.3%. The micropulse probe is held with firm pressure at the edge of the limbus. The probe is swept in a continuous motion, treating the inferior and superior ciliary processes with 1500–2000 mW for 50–90 seconds each (Fig. 10.26.4). As with TCP, care is taken to avoid the long ciliary nerves at the 3 o'clock and 9 o'clock positions.

**Fig. 10.26.1 Diode Cyclophotocoagulation Application.** The unit is portable and equipped with a semidisposable probe. (IRIDEX Corporation, Mountain View, CA.)

**Fig. 10.26.2 Tip of G-Probe.** The laser probe tip is located 1.2 mm posterior to the limbus. (IRIDEX Corporation, Mountain View, CA.)

**TABLE 10.26.1 Comparison of Treatment Parameters for Laser Cyclophotocoagulation**

	Transscleral	Micropulse	Endoscopic
Anesthesia	Peribulbar, retrobulbar	Peribulbar, retrobulbar	Peribulbar, topical, intracameral
Setting	Office, OR	Office, OR	OR
Laser	810 nm	810 nm	810 nm
Power	1.5–3.0 W	1.5–2.0 W	0.25 W
Duration	1.5–3.0 seconds	100–180 seconds total	Continuous—based on whitening
Incision	None	None	Clear cornea, pars plana
Probe	G-probe or sapphire tip	Micropulse probe	Curved endoscope
Postoperative medications	Prednisolone, atropine	Prednisolone, atropine	Prednisolone, gatifloxacin, ketorolac

**Fig. 10.26.4** Dual-function micropulse diode laser. (IRIDEX Cyclo G6, IRIDEX Corporation, Mountain View, CA.)

## ENDOSCOPIC LASER CYCLOPHOTOCOAGULATION

ECP is performed with an 810 nm diode laser, just as in TCP. The endoscopic unit is also equipped with a 175 W xenon light source that provides illumination and a helium–neon laser aiming beam (Endo Optiks, Little Silver, NJ). This fiberoptic imaging system allows for direct visualization of ciliary processes during treatment (Fig. 10.26.5). Maximum power is limited to 1.2 W, and exposure time is adjustable up to a continuous duration. Typically, starting settings are 0.25 W with continuous exposure time. The actual time of exposure is based on visual feedback of ciliary process shrinkage and whitening.<sup>12–17</sup> The procedure can be performed through a clear corneal incision, a scleral tunnel, or a pars plana incision (Fig. 10.26.6). Visibility of the ciliary processes is best in aphakia and pseudo-phakia but is limited in patients with phakia. Typically, the ciliary process is treated as completely as possible, as there is a significant portion posteriorly that cannot be treated, unless approached with the endoscope through the pars plana after a satisfactory vitrectomy has been performed. After the procedure, cycloplegics are not required, and corticosteroids are used in a similar manner to other anterior segment surgery. Follow-up is the same as for any other intraocular surgery.

## COMPLICATIONS

All forms of cyclodestructive procedures may damage ciliary muscle, ciliary epithelium, iris, and retina (Table 10.26.2). Complications include reduced visual acuity, uveitis, pain, hemorrhage, and phthisis bulbi. All complications, especially pain and inflammation, seem less severe after laser TCP than after cyclocryotherapy, and complications with ECP seem to be less severe than those of TCP. Reports suggest that micropulse diode has lower rates of serious complications, which include hypotony, phthisis, and vision loss, compared with TCP.<sup>18–20</sup> As with TCP, repeat treatments may be required, but there is no evidence that retreatment rates are higher than with TCP.<sup>18</sup>

For transscleral procedures, the occurrence of audible tissue disruptions does not correlate with success rate. Audible pops correlate with intraocular tissue disruption but not necessarily at the target tissue of the ciliary body. These are considered unwanted side effects, as is intraocular hemorrhage.<sup>21</sup> Possible causes of decreased vision include IOP spikes in the perioperative period,<sup>5,6</sup> postoperative cystoid macula edema, and progression of glaucomatous optic neuropathy in spite of the cyclodestructive treatment. The occasional gain in vision presumably results from decrease in corneal edema.<sup>5</sup> Potential complications of diode TCP include conjunctival surface burns that occur when tissue debris becomes coagulated on the tip, and with increased perilimbal pigmentation, but these heal quickly.<sup>4</sup> A higher incidence of persistent hypotony and vision loss has been reported in neovascular glaucoma.<sup>22,23</sup> Corneal graft failure is a significant problem after cycloablation for refractory glaucoma. It has been reported to occur in 11%–44% of patients.<sup>4,24</sup> Hyphema and vitreous hemorrhage are rare. Phthisis, hypotony, and loss of visual acuity may become chronic complaints.

**Fig. 10.26.5** Endoscopic view of ciliary processes with endoscopic cyclophotocoagulation (ECP).

**Fig. 10.26.6** Probe placement through the clear corneal incision with endoscopic cyclophotocoagulation (ECP).

The potential complications of ECP include all risks listed except for conjunctival surface burns; however, these complications appear to occur at a much lower rate compared with TCP. In addition, ECP carries the risk of damage to the crystalline lens, zonular rupture, and the inherent risks of an intraocular procedure, which include retinal detachment and endophthalmitis.

## OUTCOME

Diode TCP has been reported to produce results equivalent to prior technologies (i.e., cyclocryocoagulation and Nd:YAG cyclophotocoagulation—IOP

TABLE 10.26.2 Complications of Cycloablative Techniques

	Transscleral Cyclophotocoagulation	Micropulse Diode Cyclophotocoagulation	Endoscopic Cyclophotocoagulation
Conjunctival burn	++	+	0
Hyphema	+	+	+
Inflammation	+++	++	++
Pain	++	++	+
IOP spike	++	++	++
Cataract	++	+	+
Pupil abnormality	+	+	++
Hypotony	+	0	0
Need for retreatment	+	++	++
Loss of visual acuity	++	+	+
Vitreous hemorrhage	+	+	+
Choroidal detachment	+	+	+
Phthisis	++	0	+
0, never; +, rare; ++, sometimes; +++, frequent. IOP, Intraocular pressure.			

less than 22 mm Hg in 60%–84% and re-treatment rate of 28%–45%)<sup>25,26</sup> while offering certain technological advantages. Postoperative complications, including pain, inflammation, hyphema, and phthisis, have been reported to be less common than in other cyclodestructive procedures. Three different kinds of lasers (diode laser, free-running Nd:YAG laser, and continuous wave mode Nd:YAG laser) were compared in patients with neovascular glaucoma. Diode TCP had the best success in lowering IOP in 55.9% of patients after 3 years with the fewest complications.<sup>26</sup>

The literature on micropulse diode is more limited because this is a newer technology. A prospective study of 48 patients were randomized to receive either TCP or micropulse, and those in the micropulse group demonstrated a significantly higher success rate (75%) compared with the TCP group (29%) at 1 year, although this difference was not maintained through 18 months of follow-up. However, the micropulse group had significantly lower complication rates, including hypotony and vision loss, compared with the TCP group.<sup>18</sup> Although further studies are needed, micropulse is a promising new modality with an improved side-effect profile compared with TCP.

Studies evaluating ECP for treatment of refractory glaucoma used 500–900 mW for 0.5–2.0 seconds over a mean 245° of the ciliary body.<sup>14</sup> Mean decreases in IOP of 34% were reported. The studies showed that visual acuity improved or remained stable in 94% of eyes, whereas 6% lost two or more lines of acuity. Postoperative complications included anterior chamber fibrin, hyphema, cystoid macular edema, and choroidal effusion. No hypotony or phthisis was observed.

ECP has been compared favorably with the Ahmed valve, with IOP decreasing to 14.7 ± 6.4 mm Hg compared with 14.0 ± 7.2 mm Hg, with the ECP group less likely to have serious postoperative complications, including choroidal effusions and shallow anterior chambers.<sup>27</sup> In studies of pediatric patients with glaucoma, Neely and Plager reported on 51 ECP
